The grooved *director*, fig. 143, is indispensable for laying open sinuses and fistules, in exposing arteries, and in dividing the coverings of herniæ and of deep-seated tumors. It is generally blunt at the extremity, but in some cases it must be somewhat sharp, so as to effect more easy penetration of the tissues. The double director, fig. 144, is very serviceable in operating for strangulated hernia and in the extirpation of tumors with unusually firm and extensive adhesions.

Fig. 143.

The *trocar*, represented in fig. 145, and so called from the circumstance of having a three-edged extremity, consists of a cylindrical rod, passed through a silver canula. It

is employed for drawing off various kinds of fluids, as serum and pus. Its use, at the present day, is chiefly confined to the removal of water from the chest, abdomen, and vaginal tunic of the testicle. There is a contrivance of this kind with a flat, spear-shaped extremity, but it is not much employed, its canula being more liable to obstruction than that of the round trocar. Special instruments are employed for particular operations.

Fig. 144.

Fig. 145.
The *pneumatic aspirator* is simply a delicate trocar attached by means of a short gum tube to a bottle, which is exhausted of air by means of a syringe, the invention of which, apparently, belongs to Palletan, although it has been claimed by other surgeons, as Dieulafoy, Potain, and Protheroe Smith. The instrument represented in fig. 146, may be advantageously employed for removing fluids from the thoracic cavity in empyema, for emptying abscesses and distended joints, and for evacuating the urine in retention from enlargement of the prostate gland, organic stricture of the urethra, and other causes. It is also used for withdrawing gas and the fluid contents of the intestine in strangulated

Fig. 146.

Fig. 148.

Potain's Aspirator.

Fig. 147.

Suture needle in fixed handle, useful in tying erectile and other tumors.

hernia, and for diagnosticating hydatids, abscesses, and serous cysts of the liver and other abdominal viscera. The trocars are of different sizes, for ready adaptation to various contingencies, and range in number from three to half a dozen. Many modifications of the original instrument are in use.

Surgical *needles* are straight, curved, round, or flat, and of various sizes, as in fig. 147. In some instances, as when it is necessary to take a deep stitch, sew up a fissure of the palate, penetrate an unusually hard structure, or encircle a deep-seated artery, it is convenient to secure the instrument to a handle, as in fig. 148. In sewing up large wounds a needle at least two and a half inches in length, perfectly straight, like a sewing needle, slender, and very sharp, will be found to be the most convenient.

For operations upon the bones, the *surgical engine*, devised by Dr. Bonwill, of this city, is destined to come into common use in hospital practice. It consists, essentially, as is represented in fig. 149, of a frame, a driving wheel, provided with a crank, and a flexi-

Fig. 149.
Bonwill's Surgical Engine.

ble arm, to the extremity of which a hand piece is fitted for the reception of the drills, burrs, and saws, the power being transmitted by a cord passing from the wheel to the hand piece. The great speed that can be imparted to the instruments, through which they are made to revolve at the rate of fifteen thousand revolutions in the minute, enables the surgeon to perform operations with great rapidity, and with comparatively little pain. The circular saw is especially useful in dividing the lower jaw, in removing the ends of the bones in ununited fracture, in facilitating the withdrawal of sequesters, and in incising

bones affected with osteomyelitis. I have found the burrs very serviceable for shaving off the alveolar process in the neuralgia of edentulous jaws, for removing tumors of the maxillæ, for making the necessary openings in excision of the second and third branches of the fifth pair of nerves, for effecting riddance of redundant callus, for the relief of certain deformities of the nose, for the removal of carious bone, and for the extirpation of the coccyx. The drills are employed for making openings for the insertion of ivory pegs or wire in cases of false joint. The reciprocating saw is useful for subcutaneous division of the long bones for the correction of various deformities. It is provided with an attachment for fixing the bone previous to the section of its ends in pseudarthrosis, when, from the comparatively inaccessible position of the false joint, it is difficult to bring the fragments through the wound, as when the upper portion of the femur is affected.

The *syringe* forms an important element in the armamentarium of the surgeon. Great improvement has taken place of late years in the manufacture of this class of instruments, both as it respects their excellence and their variety. For washing out the vagina and rectum the most eligible syringe is Davidson's, fig. 150, and the same contrivance may be advantageously used for throwing fluids, whether simple, medicated, or intended as food, into the lower bowel. The hard rubber syringe, capable of holding from half a pint to a quart, is also well adapted to the object, and there are cases in which it is to be preferred, as when an enema requires to be thrown high up into the bowels. Syringes for the urethra, eye and ear will receive separate notice in the chapters on diseases of those organs. For cleansing wounds and ulcers nothing answers so well as a tin tank, provided with a gumelastic tube from a yard to a yard and a half in length, and fitted with a delicate nozzle capable of being insinuated into any recess, however small. When the object is to wash out the vagina, or any deep cavity,

Fig. 150.
Davidson's Syringe.

Fig. 151.
Vaginal Syringe Nozzle with Reverse Current.

covered with blood or adherent secretions, a large nozzle with numerous large apertures may generally be used with advantage. A syringe nozzle, fig. 151, with a reversed current, is another serviceable contrivance in such a condition.

SECT. II.—INCISIONS.

It is not my intention to enter into any minute details respecting the manner of holding the knife, in operating upon the living subject, as this is a kind of information which should be acquired in the dissecting-room, in connection with the study of surgical anatomy. A few rules, concisely and plainly stated, will be quite sufficient for the purpose, and will enable any man of sense to execute, with facility, neatness, and celerity, any operation he may be called upon to undertake. Anything like a flourish for the sake of display or the hope of attracting the applause of the vulgar, is as repugnant to good taste as it is out of place upon such an occasion.

There are four principal positions in which the knife may be held for operative purposes, and with these every surgeon should make himself familiar. The annexed sketches will serve to convey a better idea of their character than any description, however elaborate. They are generally distinguished by the prefix of first, second, third, and fourth.

In the first position, fig. 152, the knife is held like a writing-pen, between the thumb

and the first two fingers, which grasp the instrument gently yet firmly at the junction of the handle with the blade, the edge being inclined downwards or upwards, according to

Fig. 152.
Fig. 153.

the intentions of the surgeon.   This position is a very common one, as it is employed in a great variety of operations, as lithotomy, the extirpation of tumors, herniotomy, and the extraction of cataracts.

In the second position, fig. 153, the handle of the instrument lies in the palm, the thumb and middle finger holding it at its anterior extremity, while the index finger is slightly extended along the back of the blade, the ring and little fingers assisting in supporting and steadying the handle.   The edge of the blade is inclined downwards or upwards, according to circumstances.

In the third position, fig. 154, the knife is held like the bow of a violin; that is, the instrument, turned away from the palm, is lightly balanced in the hand, the four fingers being applied against one side, and the thumb against the other.   In the dissection, the blade is usually held somewhat sidewise, and the operation is performed chiefly by alternately flexing and extending the wrist.

In the fourth position, fig. 155, the knife is held like an ordinary carving-knife, the handle, which inclines towards the ulnar margin of the wrist, being firmly grasped by, and almost completely concealed in, the hand, the tips of the last three fingers nearly touching the hypothenar eminence.   This position is chiefly used in the amputation of the larger limbs, and, occasionally, in the extirpation of huge superficial tumors, when the surgeon wishes to produce a rapid and brilliant effect.

The incisions employed in operative surgery may be conveniently reduced to three principal ones, the straight, curvilinear, and angular, which are the parents of all the rest. In executing these incisions certain rules should be observed, of which the most important are the following:—

Fig. 154.
Fig. 155.

1. The knife, whether a bistoury or scalpel, should be in as complete a condition as possible, being perfectly sharp and clean, and as light as may be consistent with the necessary strength; its size should also be carefully adapted to the occasion.

2. Before commencing the incisions, care should be taken to stretch, extend, or tighten the skin, which is done either by the surgeon alone, or partly by him and partly by his assistants.   Attention to this rule is of great importance in numerous operations, as it not only expedites the movements of the knife and imparts precision to the incisions, but, what is often a matter of the greatest consequence, enables us to save integument, as, for instance, in case of amputations and in the removal of benign tumors.

3. The incisions, of whatever shape, should be sufficiently large to answer the purpose, for which they are designed, being made so, if possible, before the dissection is begun, as this generally greatly facilitates the removal of the parts, or their separation from each other.   The principal exception to this rule is where the operation involves the division

of large vessels, which, if they were all wounded at once, might be productive of serious hemorrhage.

4. The superficial incisions should be of equal depth throughout, the knife being entered perpendicularly at one extremity, and brought out similarly at the other, the object being the avoidance of what is called a tail, or a partial division of the integument at each end, as would inevitably happen if the point of the instrument were introduced obliquely. A gentle but steady sawing motion of the knife should be employed rather than firm pressure.

5. In dividing the common integument, the knife should always, if possible, be carried parallel to the axis of the parts to be exposed or removed, in order that there may be no interference with any important vessels or nerves, which usually run in that direction. Another great point to be gained, in observing this precaution, is that the flaps are prevented from bagging, and so serving as receptacles for the lodgment of blood and inflammatory deposits.

6. The incisions should be made as rapidly as possible, seeing that the division of the common integument is generally the most painful part of an operation. Moreover, while they should be sufficiently extensive for the object in view, care should be taken not to make them larger than is necessary.

7. All cutaneous incisions should be made with special reference to the prevention of unseemly scars. To do this successfully is not always either easy or even practicable. As a general rule, the object is best attained by carrying the knife in the direction of the muscular fibres of the part, or in the line of its wrinkles. Thus, in operating on the forehead, the surgeon will best attain his wishes if he makes his incision horizontal, not oblique, much less perpendicular. In operating upon the lower jaw, or in extirpating tumors from this region, the incision should be so directed as to run along the base of the bone, which will thus offer the best chance of concealing the resulting cicatrice.

8. The operator, in the exercise of his functions, must be careful not to wound himself, his assistant, or his patient; an occurrence as awkward as it is unseemly, and one that will seldom happen, if everything be properly arranged beforehand.

The straight incision may be made either from without inwards, or from within outwards. The former method is usually adopted in the ordinary operations, as in the extirpation of tumors, in opening abscesses, and in the ligation of arteries. Where great caution, however, is required, as in operating for strangulated hernia, or in the removal of morbid growths in front of the neck, the incision must be made from within outwards. For this purpose a fold of integument is pinched up and held by the surgeon and his assistant, while its base is transfixed by the knife, and divided by making the instrument cut its way out. The dissection is afterwards conducted upon a grooved director.

Occasionally, as in operating about the neck, especially when the object is the removal of a large tumor at the angle of the jaw, the incision may advantageously be made in a curvilinear direction, either like an Italian *f*, or in the form of a semiellipsis,

Fig. 156.

as in fig. 156. The chief reason for this procedure is that, while it affords the operator more room, it leaves a more seemly cicatrice.

The elliptical incision consists of two curvilinear cuts, meeting at their extremities, as in fig. 157. It is chiefly employed in the extirpation of tumors, where the object is to remove along with the diseased mass a portion of redundant or unhealthy integument. The incisions are made rapidly, in the usual manner, one after the other, the skin being properly stretched, and care taken not to cut away more than is absolutely necessary, since it will otherwise

Fig. 157.

be difficult, if not impossible, to bring the edges of the wound together, after the operation is over, so as to obtain a good and rapid union. Not a little judgment is frequently required to determine, in a given case, how much integument may conveniently be preserved or removed; the surgeon, remembering how contractile the skin is, will generally be cautious how he sacrifices it. Even if the flap is unseemly immediately after the operation, a few days will generally suffice to reduce it to a proper shape and size.

Two semielliptical, crescentic, or semilunar incisions, as in fig. 158, may sometimes be advantageously made, also with the object of removing a portion of integument, as for instance, in extirpating a diseased mammary gland.

Fig. 158.

The incisions may be directed vertically, obliquely, or horizontally, as may seem most suitable. The angular incision may be used for various purposes, as in the extirpation of tumors, herniotomy, excision of joints, the exposure of diseased bone, and in the transplantation of flaps for the restoration of lost or mutilated parts. It may be made in different ways, but commonly so as to repre-

sent the shape of some letter, as in the subjoined figures, according to the exigencies of the particular case.

Fig. 159.   Fig. 160.   Fig. 161.   Fig. 162.   Fig. 163.   Fig. 164.

In dissecting up the flaps, made by these different incisions, the instrument should, as a general rule, be kept in close contact with the parts to be removed ; the knife should be swept along as rapidly as may be consistent with safety ; and good use may commonly be made of the fingers, which will in most cases be found altogether preferable to the forceps. Special regard should always be had to the prevention of hemorrhage. If well-trained, intelligent assistants be at hand, there will generally be no necessity for tying every little artery as soon as it is divided ; the instant it springs, a finger is clapped upon it, and thus the operation proceeds to its completion, when, satisfactory clearance being effected, the ligation is at once promptly entered upon, and continued until every bleeding vessel is properly secured.

When the dissection involves the exposure of an important structure, as a large artery, a strangulated hernia, or a cystic tumor, which it is desirable not to pierce, the tissues must be divided layer by layer upon a grooved director gently and cautiously insinuated beneath them ; or they may be pinched up with a pair of forceps, although this is both less elegant and less safe than the other method. In performing this part of the operation, the successive divisions must be effected in the line of the external incisions, the best knife for the purpose being a narrow, probe-pointed bistoury.

SECT. III.—AVULSION, ENUCLEATION, LIGATION, AND CRUSHING.

1. *Avulsion.*—Instead of cutting away morbid growths with the knife or bistoury, removal is sometimes effected by avulsion, or by twisting and tearing. It is in this way that the surgeon usually deals with polypoid tumors of the nose and uterus, the agent that is employed for the purpose being a suitable pair of forceps, with which the tumor is seized and broken off, by rotating the instrument gently yet firmly upon its axis. All active, sudden, or forcible pulling is avoided, as tending to inflict serious mischief upon the parts around by lacerating and injuring them to an undue extent ; or, as in the case of the nose, perhaps dragging away the turbinated bone, or, as in that of the uterus, inverting that organ, or pulling it down beyond the vulva. Moreover, copious hemorrhage, intense pain, and severe shock are liable to follow such rude measures.

Avulsion is sometimes advantageously practised in the extirpation of tumors developed in and among the tissues, especially when they are deeply situated, or when they lie in the immediate vicinity of large vessels, which it would be hazardous to approach with the edge or extremity of the knife. Under such circumstances, the finger may occasionally advantageously take the place of the cutting instrument, the connecting structures being forcibly lacerated, and the mass twisted and lifted out of its bed. This mode of procedure is often resorted to in the removal of tumors from the neck and parotid region dipping deeply down behind the base and angle of the jaw, in close proximity with the pharynx and the large cervical vessels and nerves, where a false movement with the scalpel might instantly be fatal. It is astonishing what little bleeding frequently follows operations thus performed, and how well the parts generally heal after such manipulations. One reason why there is usually so little hemorrhage is that the vessels are torn, instead of being evenly divided, as they are in the ordinary procedure.

2. *Enucleation.*—Enucleation, another species of avulsion, is often advantageously employed in the extirpation of fatty, fibrous, and sarcomatous tumors. The integument, having been thoroughly divided over the morbid growth, along with its capsule, if there be any, the diseased structures are rapidly peeled out either with the finger, or with the handle of the scalpel. In certain cystic tumors the bag with its contents may often be peeled off bodily, or its cavity being laid freely open, and its contents evacuated, the walls of the cyst may be pulled away with the forceps.

3. *Ligation.*—There are certain operations in which the removal of the diseased parts is effected chiefly through the agency of the ligature, which may be constructed of silk, flax, or gum elastic. Of this mode of procedure familiar examples are afforded in the

removal of hemorrhoidal tumors, polypoid growths of the nose, vagina, uterus, and anus, and nævoid formations about the face, forehead, and other regions of the body. The ligature may be applied either directly to the part by the fingers, or by means of a needle, and should be drawn with sufficient firmness to strangulate the included structures, as the object is to cut off the supply of blood, and cause an eschar. Occasionally the ligature is used subcutaneously, as in case of nævoid growths, often involving very interesting and complicated operations. Instead of the ligature, a silver wire is sometimes used, either by itself, or by means of a double canula, as in fig. 165.

Fig. 165.

Double Canula.

4. *Crushing.*—Parts, again, may occasionally be removed by a process of crushing, as proposed by Chassaignac, of Paris, the instrument which he has devised for that purpose being called the *écraseur;* the inventor hoping thus to meet certain contingencies in operative surgery which he, in common with others, had frequently encountered in practice, and which he supposed could not be overcome in any other manner. His chief object was to supply a substitute for the ligature in the removal of certain tumors, as hemorrhoids, and polyps of the vagina and uterus. The idea seems to have been to contrive an instrument that should combine the security of the ligature with the rapidity of the knife, thus preventing hemorrhage and pain, and promptly ridding the part of abnormal structures. The écraseur, as might be supposed, was originally rude and clumsy, but, by the ingenuity of surgeons and cutlers, has been rendered very graceful and convenient, if not absolutely perfect.

The annexed sketch, fig. 166, affords an excellent representation of the shape and construction of the instrument, as manufactured by Gemrig, Kolbé, and others of this city. It will be perceived that it essentially consists of two pieces, a sheath, barrel, or tube, either flattened or cylindrical, and of an articulated chain, attached to a steel rod, lying within the sheath, and moved by a handle. The chain is constructed upon the same principle as the ordinary chain saw, but the links are stronger and perfectly obtuse, except when it is desired to combine division with crushing, when their edges are somewhat bevelled. The instrument is made of different sizes and shapes, so as to adapt it the more readily to the various cases presented in practice. The chain, unless constructed with great care, is very liable to break, especially if used for the removal of dense, indurated structures, the division of which requires a good deal of force.

One great trouble in regard to the écraseur is the difficulty of managing the flexible chain, especially in the removal of fibrous and other growths of the vagina and uterus. To remedy this defect, Dr. J. Marion Sims has added a pair of dilating forceps with spring blades, by which this portion of the instrument is rendered so stiff that it may be introduced into almost any cavity with the same facility as a probe.

Fig. 166.
Écraseur.

The smaller variety of écraseur, in which, as represented in fig. 167, the articulated chain is replaced by one or more strands of iron wire, will be found convenient for the removal of polypoid and superficial vascular growths, as well as for laying open fistulous tracks.

The écraseur is less frequently employed now than formerly, and the class of cases to which it is more particularly adapted is much better understood. Its use, at present, is very much restricted to the removal of various kinds of tumors, especially hemorrhoidal, nævoid, and ovarian, and of the tongue, penis, prepuce, and neck of the uterus. The

Fig. 167.

Wire Écraseur.

advantages that may be fully claimed for it are, first, the rapidity of the operation, which is greater than that with the ligature, although less than with the knife, the instrument acting more powerfully upon the tissues embraced in its loop; secondly, the prevention of shock, the chain doing its work gradually and almost imperceptibly, so as hardly to afford the system an opportunity of taking cognizance of what is going on; thirdly, the protection of the part against hemorrhage, the vessels being placed in a condition similar to those in a lacerated and contused wound; and, lastly, the making of a smaller and less exposed wound than either the ligature or knife, followed by less inflammation and more rapid cicatrization.

The principal rules to be observed in the application of the écraseur are the following. In the first place, if the tumor has a broad base, it should, if possible, be pedunculated, by drawing it away from its points of attachment, and casting a ligature around it, its base having previously been transfixed by one or two stout needles. When the coverings of the morbid growth are unusually hard, or insensibly lost in the surrounding parts, a gutter may be formed in them with the knife, preliminary to the application of the chain. Secondly, the division of the tissues is to be effected slowly and gradually, not rapidly or by fits and starts, and for this purpose the handle of the écraseur should be turned only about once every ten, twenty, twenty-five, or thirty seconds. The time occupied in the entire operation must of course vary according to circumstances, from five minutes, as the average minimum, to twenty minutes, as the average maximum. The great objection to a rapid operation is the danger of hemorrhage. Thirdly and lastly, the patient, during the whole procedure, should be under the influence of an anæsthetic, otherwise the pain will be extreme, especially in the earlier stages.

The subsequent treatment is very simple. If pain arises when the patient wakes from the effects of the anæsthetic, a full anodyne is given, the part is kept at rest in an elevated position, under the influence of water-dressing, and any constitutional symptoms that may show themselves are met as they occur, precisely as after any other operation. The wound generally heals in a very short time, with very little appearance of inflammation. I am not aware that the application of the écraseur has ever been followed, in cases at all adapted to its use, by pyemia, or any grave constitutional effects, and this is certainly one of the strongest arguments that can be urged in favor of its employment.

SECT. IV.—SKIN-GRAFTING.

Cicatrization of ulcers and wounds may often be greatly accelerated by the transplantation of skin, or skin-grafting, a practice the introduction of which has been generally, but unjustly, ascribed to Dr. J. L. Reverdin, who did not call attention to it until 1869, fifteen years after Professor Frank H. Hamilton had published an account of his first operation in a paper entitled "Old Ulcers Treated by Skin-grafting," published in the New York Journal of Medicine for 1854. His patient had a large wound, caused by the fall of a heavy stone fifteen months previously, and attended with so much loss of skin, as to render Nature unable to effect a cure. To cover this gap, Hamilton transplanted a portion of integument from the opposite limb, not sufficient, however, to take in the whole surface. In three

Fig. 168.
Cutting Grafts.

months the cicatrization was complete, the new piece of skin having grown from its periphery in every direction, and in the end acquired nearly twice its original size. By this operation, which foreshadowed the whole principle involved in skin-grafting, the New York surgeon hoped to establish, as he expressed it, "a new centre of life on an oasis, from whose outer verge a true and healthy vegetation shall advance in every direction over the exhausted soil." To the French surgeon, however, is unquestionably due the credit of introducing and generalizing skin-grafting, or the insertion of minute grafts at various points of the exposed surface, now so generally practised. Availing himself of a knowledge of the physiological law that cicatrization always begins at the periphery of an open surface, he happily conceived the idea of implanting small pieces of skin upon the granulations of wounds and ulcers, in order to afford these bodies, as it were, so many points of departure for the formation of new integument by virtue of the proliferation of their own cells. A very simple plan, both bloodless and painless, which I believe originated with Professor Hodgen, of St. Louis, and which is represented in fig. 168, consists in raising portions of the skin, of the size of millet seeds, with a needle and detaching them with a small knife. The grafts, which include only the epidermis with its mucous layer, and which should be taken from the inner surface of the upper arm of the patient himself to avoid the risks of syphilitic inoculation, are then placed flat upon the raw surface, at a distance of about three-quarters of an inch from one another, and confined with a layer of patent lint, spread with simple

Fig. 169.
Skin-grafting.

cerate, and supported with adhesive strips and a roller, smoothly and lightly applied. If the granulations are uncommonly large and firm, the grafts are inserted into slight incisions, to afford them a more secure hold. The dressings are allowed to remain for four or five days, when the buds will generally be found to be firmly attached, as in fig. 169. If the buds are very small, they may be so completely imbedded and hidden in the granulations as to be quite invisible for a short time. Soon, however, a bluish-white, opaque speck appears—a little island, as it were, upon the raw surface—indicative of their presence, and of the gradual development of new cicatricial tissue. The new skin thus formed makes a firmer and sounder scar than one formed in the ordinary manner, and therefore is much less liable to fall a prey to inflammation and its consequences. One of the prerequisites to the success of this process is the existence of healthy granulations, and it is well, when the ulcer is very large, not to insert too many grafts at one time, but to trust to consecutive transplantations as more likely to answer the object, which is to impart new life and vigor to the whole surface.

Experiments performed by Guyon and others show that skin-grafting is nearly as successful when practised with epidermic scales as when it is done with bits of skin. Professor Hodgen has obtained excellent results simply by dusting the granulating surface with scrapings of this kind, which, it would seem, are capable of imbibing nourishment, and of generating germinal cells for the development of new epithelium.

It has generally been supposed that the success of skin-grafting is essentially due to the presence of epithelium; but that this is not true has been clearly proved by the experiments of Professor Howard, of New York, who has obtained precisely similar results from grafts of bits of muscle, inserted into granulating wounds.

SECT. V.—SPONGE-GRAFTING.

It has long been known that fibrinous lymph or a clot of blood becomes organized by extension into it of the bloodvessels of the surrounding tissues, those substances playing merely a passive part in situations in which they are replaced by cicatricial tissue. Recognizing these facts, Dr. D. J. Hamilton, of Edinburgh, in 1880, conceived the idea of resorting to very fine porous sponge as a framework for the construction of new material for filling up the deficiencies of ulcers and large surgical wounds; and his experiments demonstrate that a firm cicatrice, which is less contractile than an ordinary cicatrice, may be obtained in this way. The only practical objection that can be urged against this method is that the healing process does not appear to be expedited, since in one of his cases five months were required to reduce an ulcer from a diameter of five inches to that of an inch and a half. In performing the operation the wound should be

accurately filled with one or more pieces of sponge prepared by dissolving out the animal matter by dilute nitro-hydrochloric acid, subsequently washing in liquor potassæ, and then steeping in a one-to-twenty carbolic solution. A piece of protective is placed over the surface and covered with lint soaked in a one-to-twenty solution of carbolic acid in glycerine, and on this a pad of boracic lint, oakum, or antiseptic gauze is confined by a bandage. At the expiration of about five days, the interstices of the sponge will be found to be filling with granulation tissue and bloodvessels, and cicatrization will commence as soon as the new tissue has attained the level of the surrounding skin, at which time the sponge will have entirely disappeared. Throughout the treatment the wound and the discharge must be maintained in an aseptic condition, irrigation with the carbolic solution being resorted to if at any time there is a putrefactive odor. A healthy granulating surface is not an essential requisite for success.

SECT. VI.—ABSTRACTION OF BLOOD.

The abstraction of blood may be effected by scarification, puncture, incision, leeching, and cupping. The fluid is sometimes taken from a vein or an artery; the operation, in the former case, constituting what is termed venesection, in the latter, arteriotomy.

1. *Scarification.*—Scarification is performed with the lancet, scalpel, or bistoury, passed lightly and rapidly over the inflamed surface, so as to divide the engorged vessels, and thus afford them an opportunity of freeing themselves of their contents. It is employed chiefly in conjunctivitis, tonsillitis, erysipelas, and irritable ulcers, and may be repeated once a day, or once every other day, according to the exigencies of the case, the bleeding being promoted by the liberal use of warm water. In irritable ulcers of the extremities as well as in other parts of the body, scarification is an exceedingly useful practice, which I have long pursued with great advantage. The proper mode of proceeding is to immerse the limb, previously constricted just below the knee, in a vessel of warm water, and then to make from four to eight vertical incisions over the sore, extending merely through the superficial portion of the true skin. In this manner I have repeatedly bled patients to syncope, making thus a most salutary impression both upon the part and system. In granular conjunctivitis, the eyelids, especially the upper, may often be scarified with the happiest effect; and in ophthalmia, attended with chemosis, deep incisions are generally practised to relieve engorgement and prevent strangulation of the vessels of the cornea. In tonsillitis, scarification nearly always greatly mitigates the symptoms; while in erysipelas, especially in the phlegmonous variety of that disease, it forms a most important element of the local treatment, nothing else being so well adapted to remove tension and prevent gangrene.

2. *Puncturing.*—Puncturing is performed very much with the same intention as scarification. It is particularly valuable in erysipelas, active œdema, boils, carbuncles, hemorrhoids, and affections of the tonsils, uvula, lymphatic glands, scrotum, prepuce, uterus, labia, and nymphæ, its beneficial effects depending upon the amount of drainage following the operation. The best instrument for performing the operation is a very narrow, sharp-pointed bistoury, thrust rapidly into the inflamed surface, to a depth varying from a line to half an inch, according to the degree of swelling of the affected parts, care being taken to avoid injuring important vessels and nerves. In the more severe forms of phlegmonous erysipelas, as many as fifty, seventy-five, or even a hundred punctures may sometimes be made with advantage.

3. *Leeching.*—Leeching is applicable to a great variety of affections, and is, perhaps, more frequently employed than any other mode of topical bleeding. The operation, however, is not without pain, and, unless properly performed, may even be followed by danger. Thus, in epidemic erysipelas, I have known it to give rise to an attack of this disease, which speedily destroyed the patient. Sometimes, again, leech-bites degenerate into bad sores, and produce much constitutional irritation. Ill effects are most likely to arise when the leeches are sickly, or when they are applied to persons of a nervous, irritable temperament. Hence, great caution should always be exercised in their selection, as well as in the manner of using them.

The best leeches are the Swiss, German, French, and Spanish, which generally take hold with great avidity, and draw each from half an ounce to six drachms of blood, including the flow after the animal drops off. The American leeches, although much larger than the European, bite reluctantly, and suck sluggishly, on which account they are rarely used. Moreover, the wound made by the foreign leech emits four times as much blood as that made by the native; a fact not to be lost sight of in ordering this kind

of bleeding. Whatever species be employed, the rule is to divest the part of hair and dirt, otherwise the animal, which is very fastidious in its tastes and habits, will either not take hold at all, or only after much coaxing. If, notwithstanding these precautions, it is not inclined to bite, a little blood should be smeared upon the surface, drawn from the part with a delicate needle, or from the operator's own finger, previously constricted with a tight cord, or the surface may be wet with sugared water or sweetened milk. Immersion of the animal for a few minutes in beer or ale will sometimes induce it to take hold when hardly anything else will. When the number of leeches to be applied is considerable, they should be confined in a tumbler, inverted upon the part, to prevent them from crawling about ; they must not be crowded too closely together, and they must, as a rule, be allowed to remain on until they drop off of their own accord, as they will be sure to do as soon as they have " taken their fill." Their forcible separation is not only productive of pain, but sometimes leaves a portion of the jaw in the little triangular wound made by its bite, which soon becomes inflamed and irritable in consequence. The bleeding is encouraged by sponging the surface well with warm water, and then covering it with a thickly-folded flannel cloth, wrung out of hot water, and frequently renewed, for a period varying from thirty minutes to two hours, or even longer, according to the desired effect. The blood having ceased to flow, the part is sprinkled with powdered starch, and covered with a dry cloth. If there is any disposition to bleed more, or longer, than is deemed proper, the bites are covered with a piece of dry tinder, which, especially if conjoined with a little pressure, generally soon puts a stop to the effusion.

The number of leeches to be applied at any one time varies from one to several dozens, according to the intensity of the morbid action, and the age and strength of the patient. In the adult from fifteen to twenty is a good average number ; in children under five years of age, from three to six. In infants the bite of a single foreign leech is sometimes followed by fatal depression. The extraordinary delicacy of the skin, and, consequently, the great depth of the bite, are reasons why leeching should be practised with more than common caution at this tender age.

There are certain localities where leeches are inadmissible. Thus, in the first place, the face, neck, and other parts habitually exposed are, if possible, avoided, because the bites of these animals are liable to be followed by disfiguring scars, particularly objectionable in the female. Secondly, they must not be applied to the eyelids, scrotum, prepuce, labia, and nymphæ, structures abounding in loose connective tissue, and therefore readily admitting of great infiltration of blood, as well as extensive discoloration. Thirdly, they must not be placed along the course of a superficial artery, large vein, or nervous trunk ; lest they should occasion serious hemorrhage and severe pain. Fourthly, care is taken to avoid the focus of an inflamed surface, as they might seriously aggravate the morbid action, if not induce gangrene. Fifthly, it is a rule not to apply these animals in the vicinity of specific ulcers, as chancroids and open buboes, for fear of inoculating their bites, and thus propagating the specific disease. Finally, leeches should never be used upon persons affected with the hemorrhagic diathesis.

A discharge of blood by leeches for a number of successive hours is sometimes very desirable, as soon as one set drops off another supplying its place. In violent ophthalmia, croup, peritonitis, erysipelas, and bubo, there is no mode of depletion so beneficial, or so likely to put a prompt and permanent stop to the disease, as this.

In leeching the uterus, vagina, ano-rectal outlet, the nose, and inside of the cheek, the animals must be confined in a glass or wire speculum, the opening in the instrument being held upon the part from which the blood is desired to be taken.

Serious, and, indeed, frightful hemorrhage sometimes follows a leech-bite. The occurrence is especially to be dreaded in children, in whom it occasionally produces fatal exhaustion, as I have myself witnessed in two instances. The best remedies are dried tinder, bound firmly upon the part, compresses wet with a saturated solution of alum or a solution of subsulphate of iron, the application of a thick layer of collodion, and cauterization with solid nitrate of silver, cut to a delicate point, and inserted into the little wound, previously well cleansed and dried. Pressing the glazed surface of a visiting card firmly upon the orifice sometimes answers the purpose. If these means prove abortive, the edges of the wound should be transfixed with a cambric needle, and approximated by ligature ; a procedure which seldom, if ever, fails.

When the natural leech is not at hand, a tolerable substitute may be found in the artificial leech of Baron Heurteloup, consisting of a small cylindrical drill, and of a glass exhausting-tube with an air-tight piston, worked with a screw. The incision may be carried to any depth, and, if the instrument be properly managed, several ounces of blood

may thus be drawn in a very short time.   The great points to be observed are to make a free opening, and to accommodate the screw-movement to the rate of bleeding, otherwise there will be a vacuum above the column of blood, thereby interfering with its flow.

4. *Cupping.*—Cupping is by no means so eligible a mode of bleeding as leeching, being more painful, less elegant, and not so generally applicable. It is, nevertheless, when properly executed, a valuable operation, particularly in the early and declining stages of inflammation. An incipient pleurisy, pneumonia, or articular inflammation is often promptly relieved by the application of half a dozen cups; but it is chiefly in the latter stages of acute disease, after the morbid action has been weakened by other remedies, and in chronic affections, that cupping asserts its true rank as an antiphlogistic agent. It is seldom, if ever, permissible in gastritis, peritonitis, and enteritis, on account of the great pain produced by the application of the scarificator. The operation, to be really serviceable, should be performed as near to the seat of the disease as practicable, care being taken not to open any large vessel, to prick any nervous trunk, or to wound any tendons. The surface selected for the application of the cups must be free from bony prominences, and, without being very soft, must have a good stratum of subcutaneous connective tissue, otherwise it will be impossible for the cups to maintain their hold, and extract a sufficient amount of blood. If the part is thickly covered with hair, it must previously be shaved.

Fig. 170.
Scarificator.

The scarificator, fig. 170, usually employed for cutting the skin, is provided with eight, twelve, or sixteen little blades, moved by a common spring, and so arranged as to make a corresponding number of incisions, none of them being deep enough to extend entirely through the cutaneous tissue, lest the fatty matter, projecting into them, should fill up the little orifices, and thereby impede the flow of blood.   The cup is capable of holding from one to two ounces; it is bell-shaped, and is composed of glass, having a large mouth, with a stopcock at the other end, to adapt it to a syringe for exhausting the air, as in fig. 171.   When such an apparatus is not at hand, the ordinary cupping-glass may be used, or any still more simple contrivance, the air being rarified by inverting the vessel over the flame of a lamp, or by means of a little pellet of cotton, wet with alcohol, and set on fire in the glass.   In a few moments the skin rises and forms a red, conical swelling, which is now scarified, the cup being immediately replaced, and allowed to remain until the coagulum in its interior arrests the flow of blood, when it is carefully removed, to be again replaced as soon as the incisions have been freed from obstruction.   If the bleeding cease before the requisite supply has been obtained, the surface is cut crosswise, and the operation proceeded with as previously.   As much blood having been drawn as may be considered proper, the glasses are removed, and the parts covered with a soft cloth moistened with oil. The number of cups varies from one to a dozen, according to the desired effect.

Fig. 171.

Cupping apparatus.

The most elegant and convenient contrivance, by far, is one made of the body of the ordinary glass cup, surmounted by a cone of vulcanized India-rubber, as seen in fig. 172. In order to apply it, all that is necessary is to indent the top with the finger, the removal of which permits the part instantly to regain its former position, thus exhausting the air within, as it does with great force and efficiency.

Fig. 172.

Cupping-glass with Vulcanized India-rubber top.

Although cupping is generally a perfectly safe operation, instances have occurred in which it was followed by annoying, if not fatal, hemorrhage. Such a result is most likely to happen when a superficial artery, as, for instance, the temporal, has been penetrated, when the blood has lost its coagulability, as when there is some idiosyncrasy, or when the system has been exhausted by protracted disease, as typhoid fever, a severe wound or a compound fracture.   The treatment must be conducted upon the same principles as in bleeding from leech-bites.

5. *Venesection.*—Venesection is commonly regarded as so trivial, simple, and easy an operation, that it has rarely received the consideration and attention to which its in-

trinsic importance really entitles it. Everybody, no matter whether he has any knowledge of the anatomy of the parts involved in the operation, or the slightest skill in the use of instruments, is supposed to be capable of performing it, and it is, therefore, often done in the most bungling manner, entailing much suffering, if not loss of limb and life, upon the patient, and great discredit, if not ruin, upon the practitioner. During the reign of the lancet accidents from its use were sufficiently common, and, for a time, I had quite my share of them, although, fortunately, not as the result of my own bad luck. Thus, in two cases I saw the patients perish from phlebitis; in five, I was obliged to tie the brachial artery at the bend of the arm; in several, great and protracted suffering ensued from the puncture of a nerve; and in three instances the arm was endangered by erysipelatous inflammation, followed by immense abscesses, and great impairment of the functions of the elbow, wrist, and finger joints. The character of the operator is sometimes seriously injured by these mishaps. It is related of Maréchal, who flourished in the reign of Louis XIV., and who was styled, by one of the poets of his day, the prince of surgeons, that he suffered greatly in his reputation for several years, on account of a fatal accident which followed the bleeding of a foreign nobleman.

A vein may be opened with a spring lancet, a thumb lancet, or a bistoury, according to the whim, fancy, or habit of the operator. I have myself been so long accustomed to the use of the first of these instruments, that I seldom employ any other. Experience has taught me that the operation, when done with the spring lancet, generally answers every purpose, as it respects the size and shape of the orifice, the safety of the parts, and the facility of manipulation, while it is incomparably less painful than when it is performed with the thumb lancet or bistoury. These are, I think, important desiderata, which no unprejudiced practitioner can overlook. No one who has himself been bled with these different instruments can hesitate about his future choice. I know that the thumb lancet is generally considered as a more scientific instrument than the spring lancet; it is certainly more simple, and, perhaps, also more easily kept in order; but these advantages do not, in my judgment, outweigh the disadvantages. Both these instruments are so well known that any description of them here would be superfluous. If a bistoury be used, one of very small size should be selected, somewhat like that employed in opening abscesses, described at page 437. It should be quite narrow in the blade, slightly spear-shaped at the extremity, and not more than half an inch long in the cutting part. Such an instrument, confined in a light handle, is more elegant than the ordinary thumb lancet, as well as more easily managed, and is decidedly more surgical and scientific; a circumstance so much insisted upon by some practitioners.

Whatever instrument be employed, it should be perfectly sharp, clean, and always well washed and wiped both before and after the operation, for it is only by observing these precautions that it can be kept in proper order, and that the surgeon can hope to avoid undue irritation and other mischief in the wounded structures. The use of a foul lancet has often been a cause of death.

Bleeding at the Bend of the Arm.—In bleeding at the bend of the arm, the best plan is to select the largest and most superficial vein, having previously ascertained that the brachial artery is not in danger of being wounded, as it might be when it lies just behind the vessel, or close along its side. When the artery separates high up, one of its branches generally passes immediately under the skin, and might thus be easily opened by an incautious operator. As to the superficial nerves, it is seldom possible altogether to avoid them, whatever vein may be selected; nor is this a matter of much moment, provided they are completely divided, and not merely pricked. The veins of the bend of the arm, with the accompanying nerves, are well seen in fig. 173.

In order to distend the vein, a fillet, a yard long by an inch in width, is tied firmly round the arm, about two inches and a half above the bend, the ends being secured with a slip knot. It must not be drawn so tightly as to interrupt the circulation in the brachial artery. The patient, extending his arm at a right angle with the trunk, in a state midway between pronation and supination, grasps a common cane, a yardstick, or any other suitable object, holding the limb in an easy, gentle position. The surgeon, standing behind the limb, then pierces the vein, making the opening obliquely, and of sufficient size to furnish a free stream. The adjoining sketch affords a better idea of the manner of holding the lancet than the most elaborate description could. The surgeon uses whatever hand may be most convenient: the vein is thoroughly steadied with the finger previously to making the incision, and care is taken that the orifices of the skin and the vessel do not afterwards lose their parallelism, lest the flow of blood should thereby be seriously embarrassed, or the fluid escape extensively into the subcutaneous connective tis-

sue. Should the latter accident occur, the fillet must be immediately removed, and the requisite abstraction effected from another vein. Sometimes the blood flows sluggishly, although the opening may be quite capacious and unobstructed. When this is the case, the patient should alternately flex and extend his fingers, so as to cause energetic contraction of the muscles of the forearm, which often powerfully promotes the bleeding; or, instead of this, or along with it, the operator rubs the limb from below upwards, although

Fig. 173.   Fig. 174.

such a procedure is seldom attended with much advantage. Sometimes the flow of blood is interrupted by the protrusion of a pellet of fat into the orifice of the vein, the timidity of the patient, or the occurrence of partial syncope.

When the spring lancet is used, the instrument is held between the thumb and first two fingers, the heel being raised a little from the surface, while the fleam is gently pressed upon the distended vein. The opening is effected in the same oblique manner as in bleeding with the thumb lancet.

The blood should always be received into a large basin held by an assistant, and special pains should be taken not to soil the patient's body- or bedclothes. When the object is to make a strong and permanent impression, the blood is taken from a large orifice, the patient being in the semierect posture. If he is very plethoric, and the object is to abstract a very large quantity of blood without occasioning syncope, the recumbent posture is selected. When the requisite amount of fluid has been discharged, the fillet is untied, and the arm is wiped with a towel wet at one end, the edges of the orifice being carefully approximated and covered with a small, thick compress, supported by a narrow roller passed round the elbow in the form of the figure 8. The arm is maintained at rest in a sling forty-eight hours, as premature motion might be productive of suppuration and erysipelas.

When blood cannot be obtained from the arm, it may, in case of urgency, be drawn from a vein on the back of the hand, from the cephalic vein as it runs along the groove between the deltoid and pectoral muscles, or from the external jugular vein. Bleeding in the veins of the leg and foot is now seldom practised, although it was at one time very common, especially among the lower classes of people.

The *accidents* that are liable to attend and follow this operation are, infiltration of blood into the subcutaneous connective tissue, inflammation of the edges of the wound and of the surrounding parts, phlebitis, angeioleucitis, puncture of the nerves, and wound of the brachial artery.

a. An *extravasation* of blood beneath the skin is one of the most common effects of this operation, and may be caused by various circumstances, as the smallness of the incision, the want of parallelism between the outer and inner openings, the great laxity of the connective tissue, transfixion of the vein, and the accidental occlusion of the wound by the interposition of adipose substance. The extravasation may be diffused or circumscribed, forming in the one case an ecchymosis, in the other a thrombus. In the former variety, the blood sometimes extends along the anterior part of the limb, nearly as high up, on the one hand, as the axilla, and, on the other, as far down as the inferior third of the forearm; imparting to the skin, at first, a dark, purplish hue, and afterwards, as the fluid is absorbed, a mottled, greenish, yellowish, or sallow appearance. A thrombus is a collection of blood immediately around the wound, from the volume of a marble to that of a pullet's egg, irregularly rounded at the base, and usually somewhat pointed at the top. Both these accidents are most liable to occur in thin, emaciated subjects, in bleeding at the basilic vein, and they should always be promptly remedied by attention to the exciting cause; or, when this is impracticable, the bandage should immediately be removed, and

the requisite quantity of blood taken from another vessel. The latter procedure is particularly indicated when the infiltration is dependent upon transfixion of the vein, the presence of a pellet of fat, or unusual laxity of the connective tissue. Defective parallelism may sometimes be corrected by changing the position of the limb; and a small orifice may be enlarged by the reintroduction of the instrument. Under no circumstances, whatever may be the nature of the difficulty, should the operator attempt to promote the flow of blood by the use of the probe, inasmuch as this would inevitably be followed by mischief.

When the extravasation is slight, it will usually disappear spontaneously in a very few days; when considerable, recourse must be had to refrigerant and sorbefacient applications, particularly a strong solution of the hydrochlorate of ammonia, alcohol, and water, and, in the latter stages, camphorated lotions, soap liniment, and similar articles. If matter form, or if the parts become angry and inflamed, leeches, blisters, and cataplasms may be necessary, with incisions to evacuate the effused blood and other fluids.

β. The edges of the wound, made in this operation, are sometimes seized with *inflammation* and suppuration; or, instead of this, a small abscess, conical, circumscribed, and very painful, forms immediately around it. Occasionally, especially in feeble, sickly, and intemperate persons, the morbid action assumes an erysipelatous type. The most common causes of these mishaps are a dull, rusty, or foul lancet, imperfect apposition of the lips of the wound, improper tightness of the dressings, premature use of the parts, and, above all, the contact of the fingers, after the removal of the fillet, for the purpose of preventing the further escape of blood. The latter circumstance has not received sufficient attention. The fingers of the operator, without his being aware of the fact, are often covered with perspiration and other matter, which, when brought in contact with the edges of the incision, are almost certain to irritate and inflame them. The only safe plan is never to touch the wound for any purpose, but, after the fillet is removed, to approximate its lips with a clean compress, made of old muslin, and confined by an appropriate bandage. If, despite proper precautions, inflammation and suppuration arise, the usual antiphlogistic means must at once be employed.

γ. *Phlebitis*, to a slight extent, is probably of much more frequent occurrence after this operation than is generally imagined, while the severer forms of the disease, those, which, properly speaking, constitute pyemia, are comparatively rare. It may be induced by various circumstances, of which the employment of a foul lancet is, perhaps, the most common. In one instance I knew it to be caused by probing the wound, under the supposition that it contained a piece of the fleam of a spring lancet, broken off in the operation, performed by a young and inexperienced practitioner. The patient, a man, thirty-six years of age, was laboring under bilious fever, from which, but for this unfortunate event, he would probably have recovered; phlebitis, however, set in, and in less than a week he died. In another fatal instance, the vein was opened with a thumb lancet, and the disastrous effects arose without any evident cause, the patient, a stout negress, being at the time affected with inflammation of the wrist-joint.

The symptoms of this form of phlebitis do not require special notice, inasmuch as they do not differ from those of phlebitis in general. The attack is commonly ushered in by pain, stiffness, and swelling of the affected part, and by rigors, alternating with flushes of heat, and followed by copious perspiration. The inflamed vein is gradually converted into a hard, rigid cord, the morbid action steadily pursuing its course towards the heart, its progress being indicated by a reddish blush of the skin. In some instances, metastatic abscesses form in different parts of the body, particularly in the subcutaneous connective tissue around the larger joints, if not also in the joints themselves. The symptoms soon assume a typhoid character, the mind wanders, great soreness is felt in the muscles and articulations, the patient complains of excessive prostration, and death generally follows in from six to eight days from the commencement of the invasion.

The treatment consists in the application of leeches, blisters, and iodine along the course of the vein, and the exhibition of calomel and opium, with the twofold object of bringing the system promptly under the influence of mercury, and allaying pain and promoting sleep. Abstraction of blood, except by leeches, is always prejudicial. Purgatives and antimony must always be avoided. If abscesses form, they must be promptly and thoroughly opened. Diffusible stimulants, tonics, milk punch, and beef essence, with an abundance of fresh air, are the proper remedies, in the event of great and rapid exhaustion. Should recovery take place, sorbefacients will be required to promote the removal of effused fluids in and around the diseased vein, which, however, despite our treatment, usually remains impervious.

δ. *Angeioleucitis* is usually produced by the same causes as phlebitis, which it also resembles in its nature, progress, and symptoms. The morbid action, still more than in the latter disease, has a tendency to extend up the limb, the course of the affected lymphatics being indicated by reddish lines, very narrow, and exquisitively tender on pressure. The disease, which generally occurs in a mild form, requires the same treatment as phlebitis, with which it is occasionally associated.

ε. Puncture of a *nerve*, whether it be a trunk of considerable size, or a mere thread-like filament, may prove to be a very serious accident. The nature of the injury is always indicated by a peculiar, stinging, burning, or pricking pain, and a sense of numbness, creeping, or formication in the distal portion of the limb. When very severe, the local distress may be attended with a certain degree of shock and a tendency to syncope, which, however, generally soon pass off. Very unpleasant secondary symptoms sometimes succeed this accident, at a period varying from several weeks to several months. One of the most common and distressing of these is neuralgia, often occurring in regular paroxysms, as neuralgia from ordinary causes in other situations. The disease is then liable to be exceedingly severe and obstinate, often resisting, for months, and even years, the best directed efforts at relief. In the cases which have fallen under my observation, it has usually been accompanied, especially in its earlier stages, with considerable swelling, numbness, and stiffness in the distal portion of the limb, together with exquisite tenderness on pressure along the course of the affected nerve. I have never known tetanus to follow this accident, but such an occurrence is not impossible, particularly in a person of a nervous, irritable temperament, laboring, at the time of the injury, under disorder of the digestive organs.

The milder effects of this injury usually pass off in a very short time without any remedial measures, simply by attention to rest and elevation of the limb. When the case is obstinate, recourse is had to anodyne and astringent fomentations, the application of iodine and even blisters, purgatives, light diet, and other antiphlogistic means. The bandage is often of great service, especially when there is considerable swelling. When the pain is of a neuralgic character, quinine, strychnia, and arsenious acid will be indicated, and, if given persistently, and in suitable quantities, will be of immense benefit. When the suffering is extremely violent and intractable, the best remedy is division of the affected nerve, as near as possible to the seat of the injury, by the subcutaneous method; or, when this is impracticable, by exposing the nerve first, and then severing it. Occasionally it becomes necessary to remove a small portion of the affected nerve, especially if, as now and then happens, it is expanded into a little nodule, or is exquisitely tender and sensitive on pressure.

ζ. A wound of the *brachial artery*, always a very serious accident, may be very slight, amounting to a mere puncture, or it may be several lines, half an inch, or even an inch in extent, as in a case under my observation some years ago. The direction of the wound may be oblique, longitudinal, or transverse, according to the manner in which the instrument is held at the time of the operation. Occasionally the artery, instead of being pierced or stabbed, as it ordinarily is, is transfixed; a circumstance which always seriously complicates the case.

The immediate effect of this accident, which is always denoted by the impetuous saltatory nature of the stream, and by its scarlet complexion, is to send the blood into the connective tissue, forming a soft, dark-colored, circumscribed tumor, or a diffused swelling, which may involve the greater portion of the anterior surface of the limb from the middle of the forearm to within a short distance of the axilla. Such an occurrence is always formidable in its character, alarming to the patient, embarrassing to the surgeon, and liable to be followed by the worst consequences.

The treatment of this accident is by systematic compression, when the opening is small, and by ligation of each extremity of the artery, when it is large.

Bleeding at the Jugular Vein.—The opening of this vessel, fig. 175, may become necessary in cases of great urgency, as in sudden and severe apoplectic seizures, and in violent inflammation of the brain, eye, and ear. In general, however, it may be dispensed with even here, the requisite quantity of blood being more easily obtainable at the bend of the arm. The patient's head being firmly supported upon a pillow, and inclined a little upwards and towards the opposite side, the vein is made to raise by pressure with the finger or thumb, applied immediately above the clavicle. The lancet is then introduced about midway between this point and the jaw, and carried obliquely upwards and outwards, so as to divide the fibres of the platysma myoid muscle crosswise instead of vertically, as this affords the edges of the wound a much better chance of retracting. A pasteboard

trough or glass tube may be used to guide the blood into the receiver. The pressure below the orifice should not be removed until the operation is completed, lest air should pass

Fig. 175.

Bleeding at the Jugular Vein.

into the vein, and thus destroy life. The requisite quantity of blood having been drawn, the wound is covered with a few strips of adhesive plaster, aided, if need be, by a compress and bandage carried round the neck and shoulders.

Bleeding at this vein in the child is peculiarly embarrassing. The best mode of performing it is to place the patient's head between the surgeon's knees, the body and limbs being firmly held by the nurse, otherwise the blood will not only flow very imperfectly, but spirt over every one present. The vein, compressed against the first rib, should be opened quite freely. A compress and a few adhesive strips, lightly applied, constitute the proper dressing.

Bleeding at this vessel in the child is not practised sufficiently often. It is particularly applicable to violent affections of the brain, larynx, and lungs, and might, in most cases, advantageously take the place of venesection at the bend of the arm, the veins of which are generally opened with great difficulty, especially in very fat subjects.

Bleeding at the Ranine Vein.—Bleeding at this vessel was formerly quite fashionable, and is no doubt entirely too much neglected at the present day. It is said to have been performed by the elder Mestivier, during a practice of twenty years, nearly fifteen hundred times, and generally with very gratifying results. It is alluded to by many of the older writers, but was in great measure forgotten until attention was recalled to it by Cruveilhier. The operation has been found particularly serviceable in acute affections of the tongue and salivary glands, the tonsils, palate, fauces, larynx, and lymphatic glands about the jaws and throat. The two veins may be opened in immediate succession, or, if the case present no special urgency, one alone may be punctured; and, as they lie immediately beneath the transparent mucous membrane, at the side of the frenum, the operation may always be performed without any risk to the ranine arteries. The incision may be transverse, and extend completely across the vessel, as suggested by Aran, or it may be made in the direction of its length, which, perhaps, is generally preferable, as the blood will then issue in a larger stream and for a longer time. In this way several ounces of fluid may usually be readily obtained. The bleeding may, if necessary, be encouraged by rinsing the mouth frequently with warm water. If the discharge is more copious than is desirable, a lump of ice laid under the tongue will generally promptly arrest it.

The patient, during the operation, should sit upon a chair or the edge of the bed, and the tongue should be gently pressed against the incisors of the upper jaw. In children,

Fig. 176.

Bleeding at the Temporal Artery.

it will generally be necessary to draw the tip of the organ out of the mouth with a dry cloth.

I have thus briefly described this operation in the belief that it may often be advantageously practised in the class of cases above alluded to. It certainly deserves to be revived.

6. *Arteriotomy.*—This operation is occasionally necessary in urgent affections of the brain and eye, and is usually performed upon the anterior branch of the temporal artery, a vessel which possesses the twofold advantage of being very superficial, and at the same time resting upon a resisting bone. Feeling for the artery, in front of the temple, the surgeon employs firm pressure upon it with the finger, so as to steady it properly, while he makes the requisite incision with a small bistoury, carried obliquely across the vessel, care being taken to cut the parts in such a manner as to admit of a full and rapid stream. A sufficient amount of blood having flowed, the artery is completely divided, in order that its extremities may retract, and thus prevent the formation of an aneurism, an effect of which I have seen several examples. A small, thick

compress is then placed upon the wound and firmly secured by a bandage, carried round the head in the manner represented in fig. 176.

SECT. VII.—TRANSFUSION OF BLOOD.

Transfusion of blood from the veins of one person into those of another is imperatively demanded when a patient is rapidly sinking from hemorrhage, whether the result of disease, accident, or operation. It has hitherto been more particularly employed in profuse and exhausting flooding, and there are numerous cases upon record where it was thus instrumental in preserving life. In such an event it is the last resource of the obstetrician, and no one should hesitate to perform it, even although the woman should literally be in the act of dying, or when, to borrow the language of an eminent writer, " the vital spirit is fluttering with tremulous delay upon the lip." Instead of blood, saline fluid is sometimes transfused, as in attacks of Asiatic cholera, attended with excessive prostration, consequent upon the rice-watery discharges from the bowels effectually draining the vessels of their serous contents. The intravenous injection of milk, to which attention has been especially directed by T. Gaillard Thomas, is liable to be followed by fat embolism, and should, therefore, only be resorted to when blood cannot be obtained from a healthy person.

The operation in question requires great care and skill for its successful execution. The chief danger to be guarded against is the entrance of air into the vein, the smallest quantity of which might prove destructive. As ordinarily performed, it is necessary to have at hand, besides a lancet, a tumbler and a glass syringe, the latter being in complete working order. The person from whom the blood is taken must be in good health, and free from all constitutional taint. The arm being tied up, and the vein opened, the blood is allowed to fall into the tumbler as it stands in a basin of water, at a temperature of about 100°, lest the fluid should coagulate, and thus become unfit for use. As soon as about two ounces have been drawn, it is sucked up into the syringe, the nozzle of which is then inserted into the patient's vein, the median basilic, for example, previously exposed by an incision at least an inch in length, and raised upon a probe. In this manner one portion after another is cautiously thrown in until from twelve to sixteen ounces have been transfused, a quantity which it will seldom be judicious to exceed. Should the pulse flag during the operation, or convulsive tremors arise, the proceeding must immediately be suspended, as it is an evidence that injury instead of benefit is accruing.

A great number of contrivances have been devised for imparting to this operation a more scientific character than when it is performed with the ordinary syringe. The method, however, here described will generally be found to answer every purpose, combining, as it does, simplicity with convenience and safety.

When greater nicety is aimed at, the apparatus represented in fig. 177, and constructed, at my suggestion, by Mr. Gemrig, may be used. It consists of a small cupping-glass and

Fig. 177.
Author's Transfusing Apparatus.

syringe, with a gum-elastic tube, about eighteen inches long, having a stopcock at its distal extremity, which is surmounted with a nozzle cut off obliquely, like the barrel of a pen. The patient's vein having been exposed by an incision and freely opened, the nozzle is inserted into it, and securely held by an assistant. A vein is then punctured in a healthy person's arm, but the blood is restrained from flowing by the pressure of the finger applied some distance below, until the cup has been placed over the orifice and exhausted

of air by means of the syringe. As soon as this has been done, the stopcock is turned, so as to permit the fluid to pass readily from one vessel into the other.

Professor Hueter, of Greifswald, is an advocate of arterial transfusion, as he is convinced that in this method the blood is conveyed to the heart more slowly and equably than in venous transfusion, in which the sudden disturbance of the circulation has occasionally been the cause of death. Another advantage possessed by arterial transfusion is that if a small quantity of air gains admission into the current of blood, it does no harm, but is absorbed, at the same time that the dangers of phlebitis are thus avoided.

The radial artery above the wrist, or the posterior tibial under the malleolus, should be isolated to the extent of about an inch, and be surrounded by four ligatures, one of which is intended as a reserve ligature in case of accident to the others. The thread nearest the heart is first tied, and the syringe having been filled with blood, the peripheral ligature is somewhat tightened, to cut off the collateral supply of blood. At this moment the artery is divided through about half of its caliber with the scissors, and into the gaping wound the point of the syringe is inserted and secured by the third ligature. The second thread being then loosened, the piston of the syringe is put into action, and when the injection is completed, the thread is permanently tied as an ordinary ligature. The artery itself is divided close to the central and peripheral threads, and the portion attached to the canula of the syringe removed with it.

The transfusion of defibrinated blood into the peritoneal cavity for the relief of various affections has within the last few years been practised by a number of physicians, attention having originally been called to it by Ponfick. The operation, which should be performed under antiseptic precautions, is easy of execution, and generally devoid of danger. The only instruments required are an ordinary trocar connected with an elastic tube provided with a glass funnel, through which the defibrinated blood is thrown through the linea alba into the abdomen. Anemia, whether caused by loss of blood or protracted disease, as pulmonary phthisis, carcinoma, syphilis, or typhoid fever, is the disease mainly demanding, and likely to be benefited by, this mode of transfusion.

SECT. VIII.—HYPODERMIC INJECTIONS.

To Dr. Alexander Wood, of Edinburgh, the profession is mainly indebted for having utilized, if not actually originated, the hypodermic method of treatment, now so widely and so successfully employed in this and other countries. Its great certainty renders it a most valuable resource in many cases and forms of disease that could hardly be reached in any other way, while the effect of the remedies thus employed is far more rapid and powerful than when the same articles are administered by the mouth or the rectum.

The medicines that are most commonly used in this way are anodynes; but they need not necessarily be of this character, as various other agents may be equally successfully injected. Arsenic, strychnia, quinine, atropia, duboisia, aconite, belladonna, and kindred articles are daily thrown under the skin, and the list of remedies thus introduced into the system will no doubt be eventually very much extended. Subcutaneous injections of quinine have been very successfully employed in numerous cases of intermittent fever, a solution of five grains thus administered being fully as efficacious as five or six times that quantity given in the usual manner, at the same time that relapses are much less frequent. Arsenic has been similarly employed. In the nocturnal incontinence of urine of children few remedies are so efficacious as subcutaneous injections of belladonna. Morphia introduced under the skin generally dispels the most agonizing pain of every description within a few minutes. Excessive gastric irritability is usually promptly allayed by this method of medication; and I know of no remedy that so speedily and effectually relieves the intolerable anguish caused by the twitching of the muscles in fractures, dislocations, amputations, resections, gunshot wounds, and inflammation of the joints, especially coxalgia. Spasm of the eye after the operation for cataract and artificial pupil generally yields in a peculiarly happy manner to morphia employed in this way. Of late the hypodermic injection of bichloride of mercury has met with a good deal of favor as a remedy in the treatment of constitutional syphilis.

In using any medicine hypodermically, it is of the utmost importance to remember that the quantity required is much less than when the same article is given by the stomach or the rectum. Thus, even when a patient is in great agony, a quarter of a grain of morphia may usually be considered as a full dose, whereas double that quantity might be required if administered in the ordinary manner, and so with all other agents

whatever. Repetition may be safely effected several times in the twenty-four hours, or, in urgent cases, as when there is intense pain, in rapid succession.

The operation is performed with a portable syringe, fig. 178, capable of holding about one drachm of fluid, and furnished with a slender, delicate nozzle, bevelled off obliquely to a very sharp point. Some practitioners prefer a graduated instrument, but such a contrivance possesses no advantage whatever over the ordinary one. The best hypodermic syringe now in use, one least liable to get out of order, is that devised by Dr. Dowler, of Brooklyn, and described in the New York Medical Record for 1879. In performing the operation, a fold of skin, pinched up with the thumb and forefinger, is pierced at the base with the sharp point of the nozzle, which is then pushed on into the connective substance beneath, followed by the medicated fluid. The moment the instrument is withdrawn a finger is placed upon the puncture, while with another finger the fluid is pressed about until the elevation produced by it has been completely effaced, as the object is to promote its speedy absorption by bringing it into contact with as large an amount of tissue as possible. The medicine, whatever it may be, is mixed with nearly a drachm of cool water, and great care is taken that there is no air introduced along with it. It is not at all important that the place selected for the operation should be near the seat of the pain or of the disease for which it is performed; the most convenient points are the back of the arm and the corresponding part of the forearm, where there are no large veins, which must always be avoided, lest the medicine, passing directly into the circulation, should endanger life by the rapidity and violence of its action. For the same reason, if a very potent remedy be used, the injection should be performed very slowly, so that, if unpleasant symptoms arise, the operation may at once be stopped, or the fluid be even sucked out.

Fig. 178.
Hypodermic
Syringe.

Hypodermic injections are not always, so far as the tissues where they are made are concerned, wholly harmless, especially when they contain irritating substances. A number of cases of tetanus, induced by hypodermic injections of quinine, dissolved in water with the aid of a little aromatic sulphuric acid, for the cure of intermittent fever, have been reported; and instances in which the puncture made in the operation was followed by erysipelas, abscesses, painful ulcers, and other distressing local effects have been witnessed by different observers. Hard nodules sometimes form, giving the surface a rough tuberculated appearance; and cases have been reported in which the puncture gave rise to fatal pyemia.

SECT. IX.—VACCINATION.

The surgery of vaccination is very simple. It may be performed either with lymph removed between the sixth and ninth day, or, what answers nearly equally well, with the dried scab rubbed upon a plate of glass, with tepid water, until it is of a thin consistence, and of a very pale milky hue. The matter is taken up with the point of a sharp, narrow lancet, represented in fig. 179, a tenotomy knife, or a common needle, and inserted into the skin on the outer surface of the arm, just below the deltoid muscle, or on the outer and upper part of the leg at a suitable distance from the knee, at two spots, each about the diameter of a three-cent piece, and sufficiently far apart to prevent them from running together during the height of the resulting inflammation. The impregnation may be effected by a number of little punctures, by three or four superficial incisions, or, simply, by a slight abrasion of the epidermis. Whatever method be adopted, no blood should be drawn, as it might wash away the vaccine matter. When the operation is performed with lymph taken up on bits of ivory, a procedure which some practitioners prefer to any other, the points should be held for a few seconds in the steam of hot water, and then rubbed upon the raw surface.

Fig. 179.

Vaccine Lancet.

The wound, on the third day after a successful operation, is found to be slightly inflamed and elevated; and on the fifth day a characteristic vesicle appears, of a beautiful pearl-colored aspect, circular or oval in shape, and occupied by a drop of thin, limpid fluid. On the eighth day the vesicle is in its greatest perfection; it is now somewhat of a yellowish hue, distinctly cellulated in structure, very prominent, slightly umbilicated at the centre, and surrounded by a circular areola, the skin around being inflamed, tense,

and painful. Occasionally considerable swelling of the glands of the axilla exists. The constitution is now thoroughly implicated, and, as a consequence, the patient is feverish and restless. On the eleventh day the areola begins to fade, and the vesicle, which usually spontaneously bursts, gradually dries up into a hard, brownish, circular scab, which, dropping off from the eighteenth to the twenty-first day, leaves behind it a small, rounded, pitted, and indelible cicatrice, attesting the success of the operation.

Vaccination may be performed as early as the sixth week after birth, and at all periods of life subsequently. If the child is sickly, the general health should previously be amended, particularly if there be any eruptive disease. Some persons evince the most remarkable insusceptibility to the influence of the vaccine virus. I have seen a number of cases in which the operation was performed upwards of twenty times before it finally succeeded. Healthy children afford the best lymph, and the matter of primary is more energetic than that of secondary vaccination.

Lymph taken from the cow is now commonly preferred ; it is usually collected upon the end of a quill or a piece of ivory, and is softened with cold water immediately before it is inserted or rubbed upon the surface. Six or eight superficial incisions merely carried through the epidermis in a vertical direction are generally quite sufficient. Bleeding must be prevented. The lymph must be kept in a dry place.

The bad effects of the operation are, 1st, too much local action, the inflammation sometimes assuming an erysipelatous character ; 2dly, severe inflammation of the axillary glands ; 3dly, ulceration, or even gangrene, at the seat of the vesicle, leaving a sore which is occasionally very tedious in healing ; 4thly, a lichenous or roseolar eruption, attended with distressing itching, and often considerable swelling ; and 5thly, an appearance of vesicles upon the general surface, resembling those of varicella, or even those of genuine cowpox. The regular development of vaccinia is sometimes retarded by the preoccupation of the system by other affections, as measles and scarlatina.

It is impossible to exercise too much care in the selection of vaccine virus. To a want of this precaution may be ascribed most of the bad effects that follow the operation. A number of well-authenticated cases have been recorded during the last twenty years in which it gave rise to syphilis in its very worst forms.

The effects of vaccination are sometimes completely lost, in the proportion, probably, of about forty persons in one thousand. It is for this reason that the operation should be occasionally repeated.

SECT. X.—COUNTERIRRITATION.

Counterirritation may, as stated elsewhere, be established in various ways, as by rubefacients, vesicants, and dry cupping ; but when the object is to make a deep and protracted impression, the means usually selected are the permanent blister, the seton, and the issue. Sometimes the moxa and acupuncturation are employed.

1. *Rubefacients.*—A rubefacient effect, or temporary irritation of the skin, may readily be produced by a great variety of articles, as mustard, ammoniated liniments or unguents, spirits of turpentine, chloroform, hot water, and the hot iron. The latter, in the form of the objective cautery, as the French term it, consists in passing a piece of iron, heated perfectly white, rapidly over the surface at a distance of three to five inches. The skin becomes almost instantly red, and if the application be continued for a few minutes, vesication follows.

Mustard is generally applied in the form of mustard-paper, kept for ready use by the apothecary, and cut into suitable strips as it is needed. A mustard plaster may be made of mustard flour, mixed with water at a temperature of $90°$ to $100°$. If the water is too hot, it will coagulate the albumen ; if too cold it will prevent the disengagement of the oil upon which the irritating properties of the mustard depend. As more or less of the mustard is liable to adhere to the skin, the best plan always is to interpose a layer of gauze, or very thin muslin, wrung out of warm water. The time during which the application should be continued must vary, on an average, from ten to twenty minutes, according to the effect desired. Great care must be exercised in the use of sinapisms in children and in persons generally of very delicate skin, as well as in patients worn out by disease and intemperance, otherwise serious mischief may ensue. The smarting, burning pain which so often follows their application is commonly promptly relieved by lead-water, olive oil, or iced water.

A very useful and speedy rubefacient action may be produced by means of Dr. Corri-

gan's button cautery, fig. 180, heated in the flame of a spirit lamp until the forefinger, resting upon the shank of the instrument near the disk, begins to feel uncomfortably hot, the period usually required not exceeding a quarter of a minute. As soon as it is ready, it is applied as quickly as possible, the skin being tipped successively, at intervals of half an inch, over the whole of the affected part, which soon assumes a bright red appearance, and becomes the seat of a glowing sensation. The disk of the instrument is half an inch in diameter by three lines in thickness, with a flat surface, and a thick, iron-wire shank, two inches in length, and inserted in a small wooden handle.

Fig. 180.

Very efficient counterirritation may be produced by the actual cautery, heated to a white heat, and drawn lightly, but rapidly over the surface near the seat of the morbid action, at several points, for a distance of two to three, four, or even six inches. The application is immediately followed by reddish-brown welts, surrounded by a zone of scarlet, indicative of hyperemia. The pain is generally very insignificant, and there is seldom any vesication. The epidermis in a few days drops off in dry scales, leaving a slightly brownish stain, which soon disappears. The remedy is particularly valuable in neuralgia, gout, and rheumatism, and in superficial inflammations of the joints and other parts of the body. The cautery should be tipped with platinum, as it will thus preserve its smoothness, a desideratum of great importance.

2. *Dry Cupping.*—Dry cupping is occasionally employed, especially in chronic affections, in which it is often of great value. The air being exhausted, as in the more common operation, the cup is allowed to remain on the part for a period varying from thirty to forty-five minutes. At the end of this time it will generally be found that there is not only a marked afflux of blood, but likewise more or less vesication of the skin, objects which the practitioner should always endeavor to attain whenever he advises such an operation; for, unless it be performed efficiently, no benefit whatever will be likely to result from it.

Corrigan's Button Cautery.

Dry cupping is particularly serviceable in chronic disease of the brain and spinal cord, the thoracic and abdominal viscera, and the larger joints. The number of cups employed, and the repetition of the operation, must be regulated by the exigencies of the case.

An instance has been communicated to me in which this operation was followed by gangrene. The patient, a soldier, was affected with typhoid fever. Four dry cups were applied over the lower part of the spine, where they were retained for ten minutes. The surface soon began to assume a livid aspect, and the integument included in two of the cups sloughed out to the depth of a quarter of an inch, the others suffering in a less degree.

3. *Permanent Blisters.*—A permanent blister is made by letting the fly remain on the skin an unusual length of time, and then divesting the part of epidermis. It is capable of furnishing a free discharge of pus, which may often be maintained for a long time, either by the occasional reapplication of the fly, or by means of some irritating ointment, as the savin or mezereon; or, what I prefer, an ointment composed of an ounce of cosmoline and three to eight drops of nitric acid. Whatever article be used, the surface should be constantly protected with an emollient poultice or warm water-dressing, otherwise the sore will become excessively irritable, and cease to furnish the desired discharge. Whenever the secretion begins to slacken, a little of any of the unguents here mentioned may be applied to the sore to renew the morbid action. I have occasionally used the dilute fly ointment for this purpose, but having several times produced strangury with it, I have latterly abandoned it.

4. *Seton.*—A seton is a subcutaneous wound, holding a foreign body. It may be made with a bistoury, and a piece of gum-elastic tape, or in the absence of this, a narrow strip of muslin, conveyed beneath the skin by mean of an eyed probe or the seton needle, represented in fig. 181. The integument being pinched up, the instrument is pushed through the connective tissue, care being taken not to interfere with any muscular fibres, tendon, nerve, or vessel. The ends of the seton are tied long,

Fig. 181.
and held out of the way by a strip of adhesive plaster. The mode of introducing a seton with knife and probe is shown in fig. 182.

An emollient cataplasm is the most suitable dressing, both immediately after the operation and subsequently, during the sojourn of the foreign body. At the end of the second day the tape is drawn gently across the wound, a fresh portion taking its place, and this process is afterwards repeated as often as cleanliness and other circumstances may render

Fig. 182.
it necessary. If the discharge becomes deficient, recourse is had to some stimulating ointment; if offensive, to the chlorides. When the tape becomes soiled, a new one takes its place. Sometimes fungous granulations spring up at the orifices of the subcutaneous wound, causing much pain and inconvenience. The best remedy is excision, followed by nitrate of silver. The insertion of a seton is usually attended with little bleeding; but I recollect the case of an elderly gentleman, a patient of a late eminent practitioner, who nearly lost his life from this cause, the operation having been performed upon the nape of the neck. The blood seemed to have proceeded from a small artery among the cervical muscles, the instrument having penetrated too deeply. Great care should be exercised in the introduction of setons in front of the neck, as the operation has been followed, in several instances, by the admission of air into the veins and the speedy death of the patient.

A seton is, on the whole, a filthy, painful, and imperfect form of counterirritation, which it might, perhaps, be well to exclude altogether from practice, as its place may always be easily supplied by the issue.

The seton is sometimes employed as a means of obliterating cavities, as in hydrocele and the so-called housemaid's knee. Great care is necessary when it is thus used that it does not provoke too much inflammation. The filiform seton, as it is termed, generally consists of a single thread.

5. *Issue.*—An issue is an artificial ulcer, intended to furnish a discharge of pus. It is adapted to the same class of cases as the seton, but is more cleanly, less painful, and more convenient. Moreover, such a sore affords a good surface for the local application of morphia and other remedies, which may often be advantageously used, in this manner, for relieving pain, as well as for other purposes.

Issues may be made in various ways, as with the knife, the Vienna paste, the galvanic and actual cauteries. The first of these methods is not sufficiently efficient to justify its general employment; it is better adapted to the scalp than to any other region of the body, and may be advantageously used in diseases of the pericranium and of the brain and its meninges. An incision being made through the skin and connective tissue, from half an inch to an inch in length, its cavity is filled with some foreign body, as a pea, grain of corn, small pebble, piece of orris root, or, what is best of all, a solid glass bead, which soon produces a pyogenic action that may afterwards be increased, if necessary, by the use of some stimulating ointment. The substance is confined with a strip of adhesive plaster and a bandage, and is occasionally replaced by a fresh one, cleanliness being maintained in the usual way.

An excellent issue may be made with the *Vienna paste*, composed of equal parts of quicklime and hydrate of potassium, thoroughly triturated together, and preserved in a closely-corked vial until required for use. The requisite quantity is then put upon the bottom of a saucer, and converted into a thick paste with alcohol. A layer, about two lines in thickness and of the desired diameter, is put on the skin, and allowed to remain for eight, ten, or fifteen minutes, according as it is desired to make a slight or deep impression. The surface, which will be found to be of a pale drab color, is washed with vinegar and water, to neutralize the alkali, and covered with an emollient cataplasm, to promote the detachment of the slough, which usually happens in from five to eight days. Some pain

attends the operation, but this is soon over, and bears no comparison with the horrible distress produced by the application of hydrate of potassium alone; besides, the Vienna paste does not diffuse itself over the adjacent parts, and thus unnecessarily destroy the skin. The extent of the issue is regulated by the extent of the layer; one of the diameter of a twenty-five cent piece affording, when the sloughing is completed, a sore two or three times that size. The best permanent dressing is a poultice; the best promoter of discharge, some stimulating ointment, or the occasional use, for a few hours, of a small blister.

What is called the "London paste" is composed of equal parts of caustic sodium and unslaked lime, converted into a powder, and kept in a well-corked vial until required for use, when it is mixed with water instead of alcohol. Its advantage over the Vienna paste is that it is far less painful and much more manageable.

The most eligible issue of all, however, is that made with the *actual cautery*; it affords not only an abundant and protracted discharge, far beyond what follows the more ordinary issue, but, what is often a matter of no little consequence, it makes an impression both upon the part and system, which no other mode of counterirritation is capable of producing. On these accounts, this kind of issue should have a decided preference over every other in all protracted and obstinate cases of disease where the employment of revulsives is indicated, as in caries of the hip-joint, Pott's disease of the spine, and similar affections, in which its powers, as a topical remedy, are unequalled.

To perform the operation properly, the iron, heated to a white heat in a small charcoal furnace, should be pressed with some degree of firmness upon the spot selected for the issue until the skin is converted into a black eschar, the patient being fully under the influence of an anæsthetic. Care must be taken not to penetrate beyond the subcutaneous connective tissue. A cloth, wrung out of cold water, is immediately laid upon the part, and frequently renewed, for a few hours, when it is replaced by a poultice or warm water-dressing. The slough usually drops off in from five to eight days, leaving a sore, which, while it is easily kept clean, furnishes a free discharge, and may be kept open, with but little care, for an almost indefinite period. A cautery the size of a half-eagle will make an issue, after the separation of the eschar, of the diameter of a silver dollar. The instrument should be fully half an inch thick, otherwise it will not retain its heat sufficiently long.

6. *Moxa.*—The moxa is a soft, combustible substance held upon the skin, and suffered to burn down slowly, so as to produce a temporary irritant effect. It may be prepared from various articles, as agaric, hemp, cotton, rotten wood, the pith of the common sunflower, and the down of the artemisia chinensis; but the one which I usually prefer is soft patent lint, soaked in a strong solution of nitrate of potassium. When thoroughly dried, this is rolled up into tolerably firm, cylindrical cones, an inch and a half long by one inch in diameter. In applying them, they should be ignited at the top, and held upon the part intended to be cauterized with a pair of dressing forceps, a long hair-pin, or a porte-moxa, fig. 183; the surrounding surface is protected with a piece of wet linen perforated at the centre. When it is desired to hasten the combustion, a blowpipe may be employed, but in general this is unnecessary. Whatever substance is used, the heat can be so graduated as to produce any amount of irritation, from the slightest rubefaction to a superficial eschar. When the latter effect is desired, the moxa should remain on until it is wholly consumed; otherwise it may be removed as soon as the pain becomes somewhat severe; or, instead of placing the burning material in contact with the skin, it may be held at a little distance from it. The eschar is of a yellowish, gray, or dark color, and usually drops off in six or eight days. The pain produced by the operation may be promptly relieved by the application of ammonia, cold water, or pounded ice.

Fig. 183.

Porte-Moxa.

The moxa seems to act on the same principle as the objective cauterization, and the ammoniated counterirritants, already spoken of, and is a valuable agent in many chronic cases, when it is intended to produce a sudden impression upon the nerves of the affected part; it should always be applied as near as possible to the seat of the malady, and the effect should be sustained for weeks, or even months, by the repeated application of the agent. The diseases in which it seems to be most efficacious are amaurosis, neuralgia, nervous deafness, partial paralysis, coxalgia, and spinal irritation.

7. *Acupuncturation.*—Counterirritation may be effected also by acupuncturation. This consists in the insertion of very slender, well-polished, sharp-pointed, steel needles, figs. 184, 185, 186, from two to four inches in length, furnished with a metallic head, or

Figs. 184, 185, 186.

a head of sealing-wax. To prevent them from breaking, they should be rather soft and flexible. They are introduced into the affected part, previously stretched, by a gentle rotary motion, aided by slight pressure, and are suffered to remain from one to six hours, according to the effect they produce, or the object they are intended to fulfil. In some instances a period of ten minutes is sufficient; in others, they may be kept one or two days. They may be carried to a depth of several inches, but care must be taken not to transfix any important viscera, vessels, or nerves, though this has often been done without ceremony, and without any injurious results. The number of needles to be used varies from one to a dozen, according to the extent of the affected part and the sensibility of the patient. The operation rarely causes much pain, and is scarcely ever followed by any unpleasant symptoms. In most cases a slight blush, which subsides in a few hours, is observed around each puncture. In withdrawing the needles, which is sometimes effected with difficulty, owing to their having become oxidized, a movement of rotation should be given to them, at the same time that pressure is made upon the adjacent surface with the thumb and forefinger.

Acupuncture Needles.

Acupuncturation has been employed in a great variety of affections, as neuralgia, rheumatism, gout, sciatica, paralysis, cephalalgia, and epilepsy; recently it has been recommended in the treatment of aneurism, hydrocele, varicocele, and anasarca. Its advantages have been much overrated, and the practice, borrowed from the Chinese and Japanese, has fallen into disrepute.

SECT. XI.—SURGICAL APPLICATIONS OF ELECTRICITY.

Electricity is employed locally, as a surgical measure, under two forms, faradism, or the induced current, and galvanism, or the continuous current, and they are termed, according to their application, faradization and galvanization. The former finds its widest and most legitimate range of employment in the treatment of paralysis of movement, of muscular atrophy, and rheumatic contractions; while the calorific properties of galvanism are utilized principally for the removal and discussion of tumors, either as an actual cautery or as a catalytic agent.

Faradization, as an antiparalytic measure, acts by restoring the impaired or lost functions of the affected muscle, by throwing it into alternate contractions and expansions, through which a more abundant supply of arterial blood is transmitted to it, promoting its local circulation, and, consequently, augmenting its nutrition.

For the proper practice of local electrization, the choice of a good apparatus is of the first importance. Without entering into a description of electro-magnetic machines, or the properties which such instruments should possess, which would be out of place here, suffice it to say the requirements of the surgeon are fully met in the portable bisulphate of mercury battery of Gaiffe, of Paris, the induction apparatus of Stöhrer, of Dresden, or, in their absence, the instrument of Kidder, of New York. The larger zinco-carbon apparatus of Stöhrer, now thoroughly appreciated in this country, is preferable. It is constituted of two cells, which may be arranged as two pairs, or as a single pair of elements, and has a much greater range of power, and more thorough means of graduating the currents, than the smaller instrument. It does not require constant attention, and is always ready to act, since, by a simple contrivance, the elements can at once be immersed or removed from the exciting liquid, through which they retain their activity for a long time.

The electrodes, or reophores, vary in form, but they are commonly metallic cups or plates, fixed to insulating handles, the former of which contain a moist sponge, while the latter are covered with wet, soft leather. The handles are provided with clamps for the attachment of the conducting wires, through which they communicate with the poles of the battery. The diameter of the electrodes varies. When a large muscle is to be acted upon, it should range from one to three inches, while for the smaller ones, as the interosseous, and for indirect muscular faradization, the diameter need not exceed one-third of an inch, and they may even be conical in shape.

In cases of paralysis the muscles may be electrified in two different ways, either indirectly through the nerves which supply them, or directly by acting upon their proper tissue. The former method, known as extramuscular excitation, produces contraction of several muscles, or of all parts of a single muscle; while the latter, termed intramuscular

excitation, provokes contraction of only one muscle, or parts of one muscle, and requires a current of greater power. In either method, both the skin and electrodes should be kept thoroughly moistened with warm water, or salt water, not only that the current may traverse the skin and concentrate its power on the deeper tissues, but also to prevent the disagreeable sensations of heat and pricking which are sure to occur when the electrodes are dry. If it be desired to act directly upon a muscle, the reophores should be applied over their fleshy bellies, and never over the tendons, and be moved near together over all portions of the muscle corresponding to the surface. If the substance of the muscle be thick, the current must be more intense than when a thin muscle is operated upon, as a weak current only produces contraction of the superficial layers. The tension of the current should also be proportioned to the thickness of the tissues to be traversed, as is exemplified in fat persons, in whom a moderate current does not reach the muscle at all.

Nothing can be more simple than direct faradization of muscles; but the same remark does not apply to the extramuscular method, in which the current is directed to the points of entrance of the motor nerves, and which requires an exact knowledge of the entrance and exit of nerves, a knowledge, it need scarcely be added, that can only be attained by repeated dissections. The points of selection for the production of isolated contractions of muscles, however, have been mapped out by Professor Ziemssen, in his work entitled, Die Electricität in der Medicin, which may be consulted with advantage by those who desire specific information on indirect muscular faradization.

Localized faradization is a remedy of great value in the treatment of traumatic paralysis; and it has also been employed, by means of peculiar forms of electrodes, for atony and paralysis of the rectum, bladder, pharynx, œsophagus, and larynx, but without any striking results, excepting in cases of aphonia from loss of power in the vocal cords.

In treating paralysis by electricity, the fact should not be lost sight of that reliance is not to be placed upon faradization alone, since muscles which refuse to respond to induced currents, sometimes evince a remarkable degree of excitability by continuous galvanic currents. In such cases local galvanization is superior as a therapeutic agent to local faradization; but with return of mobility the excitability by the continuous current is commonly gradually lost, and that by induced currents gradually returns. Under these circumstances faradic currents must be employed.

Galvanization is chiefly applicable to the discussion and removal of certain tumors, diseases of the bloodvessels, chronic glandular swellings, firm inflammatory exudations in and around joints, serous effusions, the formation of issues, and the treatment of rebellious sinuses, fistules, and ulcers.

Fig. 187.
Bunsen's Battery with the Cauteries attached.

Of the many kinds of batteries used for the generation of the galvanic current, none is more excellent, less trying to the patience of the practitioner, and, in the end, more economical, than the portable battery, with lifting apparatus, of Stöhrer, consisting of

twenty-four, or more, pairs of elements. Bunsen's battery, fig. 187, with six cells, which contain essentially the same elements as those in Stöhrer's battery, will furnish the desired amount of heat for galvanic cauterization; but the elements are generally found to be too few for the electrolytic treatment of the firmer morbid growths. In the absence of these batteries, that invented by Daniell, with which every medical student is perfectly familiar, is the best, on account of its reliability, cleanliness, and cheapness. Fifteen cells, arranged in a case, will furnish a sufficient quantity of electricity for all surgical purposes. It should be taken apart every six or eight weeks in order that the zinc may be cleansed, and the solution of sulphate of copper renewed.

Galvanic cauterization is commonly practised with the electrode of Professor Middeldorpf, an instrument which contains two gilt copper wires that communicate at the handle

Fig. 188.   Fig. 189.   Fig. 190.

Marshall's Galvanic Seton.

Galvanic Cauteries.

with the poles of the battery, while its anterior extremity terminates in a platinum wire, wrapped spirally around grooved, hollow porcelain shells, which are rendered incandescent as soon as the circuit is established. The instrument and the variously shaped cauteries are exhibited, in miniature, in the preceding figure, while two are represented of the full size in figs. 188 and 189. They are designed for the establishment of issues, the destructive removal of superficial tumors, as the nævoid and epithelial, and the treatment of epithelioma, ulceration, and other affections of the mouth and neck of the uterus; and are placed in contact with the parts while cold, when the circuit is established, and continued until the desired effect is produced. The galvanic cautery of Mr. Marshall, of London, fig. 190, will be found to be a useful instrument for the management of rebellious sinuses and fistules.

The galvanic cautery, in the form of a loop of platinum wire, is a powerful, rapid, and generally bloodless agent for the removal of superficial tumors, polyps, portions of the tongue, the neck of the uterus, and malignant growths in situations in which the use of the knife would be difficult, and attended with severe and troublesome hemorrhage. It has been employed very successfully for the removal of growths of the larynx by Dr. Voltolini, and other practitioners; but Bruns, Mackenzie, and others are averse to its use, not only on account of the many inconveniences it causes to the patient and the trouble it gives to the surgeon, but also, and more especially, for the reasons that it is very difficult to limit the action of the incandescent loop to a small surface, and that, on that account, it is liable to produce acute œdema of the glottis.

The electrolytic treatment of tumors is more universally applicable, although it is far more tedious than the preceding method. The only instruments required are fine gold, or gilt steel, needles, and a sponge electrode. In performing the operation, the needle is passed into the interior of the growth, and attached to the negative pole of the battery, while the sponge electrode, previously wet with salt water, and connected with the positive pole, is placed outside on the skin. When the tumor is small, one needle will suffice; but when it has acquired considerable volume, the serres-fines conductor of Dr. Althaus will prove serviceable, as it permits the introduction of several needles in any direction that may appear most suitable. They should be insulated to within a short distance of their points with vulcanite, so that they may not affect the skin, thereby producing unnecessary suffering and subsequent inflammation.

Although the transmission of the current is not painful, yet, to prevent any unpleasant shock, the precaution should be taken of commencing with low power, and gradually increasing it to the full quantity that it is designed to employ. The duration of the application will vary according to the nature of the case, two or three minutes being sufficient for small tumors, while larger growths require from fifteen minutes to half an hour. The sittings may be repeated every second or third day. The number of cells, or the quantity of electricity employed, must be proportionate to the consistence of the tumor; solid

goitres and scirrhus, for example. demanding from thirty to forty cells, while other growths will yield to a battery of fifteen pairs of elements.

The best results from electrolysis have been obtained in vascular, sebaceous, and goitrous tumors, particularly the cystic variety ; in chronic glandular tumors ; in hydatid tumors of the liver ; in hydrocele, and in stricture of the urethra. In the treatment of aneurism it has almost been abandoned ; but it has proved successful in several cases of the cirsoid form of the disease that have been subjected to it. Nævoid, venous, and small sebaceous tumors rarely resist the influence of the galvanic current, while the testimony of Dr. Althaus and Dr. Mackenzie is strongly in favor of it in the management of goitre, the former observer believing " that all cases of bronchocele, however large, may be cured by electrolysis, if the treatment be persevered in for a sufficient time." Dr. Fagge and Dr. Durham, some years ago, recorded eight cases of hydatid tumors of the liver, in seven of which, one remaining doubtful, a cure was promptly effected. Dr. Ruschenberger, of our Navy, Scoutetten, and Pétrequin have cured obstinate hydroceles by introducing both electrodes into the sac; while other surgeons have successfully employed electrolysis in similar instances with the cathode only in the sac. The observations of Mallez and Tripier, Brenner, and others demonstrate that good results may occasionally be anticipated from it in the treatment of stricture of the urethra. Thus, of forty-four cases, only two proved fatal, and in only two febrile symptoms were set up. Electrolysis has also been employed in carcinomatous tumors, but a more extended experience is necessary to decide its applicability in these affections.

As a mode of counterirritation, needles are sometimes introduced into the tissues for the purpose of transmitting to the affected part a current of electricity or galvanism. The operation, denominated, in the one case, electro-puncturation, and, in the other, galvano-puncturation, is performed in the same manner and with the same instruments as in the ordinary process, except that the latter have a small ring at the top for receiving the conducting wires of the poles of the battery. Only two needles are used at first, but the number is gradually increased as the patient becomes able to endure the action of the current. When it is intended to produce a shock, a Leyden jar may be employed, but for maintaining a steady effect a small horizontal galvanic pile is the most appropriate apparatus. This mode of counterirritation is almost entirely restricted to the treatment of chronic affections attended with deep-seated and inveterate pains, as gout, rheumatism, neuralgia, and sciatica.

SECT. XII.—ANTISEPTICS.

The employment of antiseptic agents has for its object the prevention and arrest of putrefaction in wounds, whether accidental or surgical, by devitalizing or rendering inactive the germs which induce it. According to the panspermic theory of Pasteur, the atmosphere is loaded with invisible living germs, which, coming in contact with the putrescible material—effused blood and plastic matter—of open wounds, induce decomposition and consequent irritation, which, in its turn, gives rise to suppuration and constitutional disorder. Hence the aim of the antiseptic method of treatment is to destroy the septic energy of the atmospheric germs, through which putrefaction and the morbid processes which result from it are prevented.

Although the researches of Pasteur, Virchow, Rindfleisch, Hueter, Vogt, Sanderson, Klebs, Cohn, Cheyne, Lister, and other observers have established the existence of myriads of low forms of organisms in our breathing atmosphere, the demonstration of living, disease-producing germs is wanting. Hence, physicians, myself included, have been somewhat chary in accepting the germ theory of the decomposition of animal matter. There is not the slightest difficulty, on the other hand, in comprehending that the atmosphere of ill-ventilated and long-occupied hospitals contains a noxious, invisible, permeable dust, holding in suspension epithelial and pus cells and other particles of organic matter, which is capable, by direct contact with wounded surfaces or open sores, of inducing putrefaction, suppuration, and their evil consequences, and also of giving rise to the phenomenon of blood-poisoning through its absorption by the lungs. During our late war I had repeated opportunities of observing the toxic effects of the tainted atmosphere of our city military hospitals, and the rapid improvement in the condition of the wounded upon their removal to the purer atmosphere of tent hospitals in the vicinity of the city. My experience, moreover, in private practice, has convinced me that abscesses may be opened, that wounds, as those made in the removal of tumors, may close, and that compound fractures may unite, as readily without as under the use of antiseptic agents, and I have, therefore,

of late, employed them, not to prevent, but merely to arrest the processes of putrefaction, and to destroy its products. In hospital practice, however, prevention should be aimed at.

Among the antiseptic agents are generally, but improperly, included certain articles which should be classed as deodorants, as chlorine, bromine, iodine, and permanganate of potassium, all of which oxidize the gaseous products of decomposition, destroying their odor, but exerting no effect upon the specific virus or septic germs. Solutions of the metallic salts, as the chlorides of zinc and aluminium, the sulphates of zinc and copper, and nitrate of lead in the form of Ledoyen's disinfecting fluid, perchloride of iron, bichloride of mercury, through oxidation of the morbific agent, and their chemical action on the tissues, must be ranked among the septicides as well as deodorizers.

A solution of *chloride of zinc*, of the strength of forty grains to the ounce, was highly recommended by Mr. De Morgan, as a permanent antiseptic, its action penetrating the tissues deeply, and forming with their albuminoid constituents a dense coagulum incapable of putrefaction. The wound, exposed tissues, or cavity of an abscess, should be soaked with the solution by irrigation and sponging, and the application need not be repeated, as its effect is permanent. Perchloride of iron, in aqueous solution, is one of the best articles of this class, as it forms a resisting, adherent coagulum, which is readily absorbable as cicatrization advances.

Chloralum, or chloride of aluminium, is a very powerful septicide and deodorizer, non-poisonous, astringent, styptic, devoid of odor and causticity, and is particularly serviceable in wounds, hemorrhages, and foul discharges, absorbing noxious gases and destroying parasites and germs. The agent in general use which it most closely resembles is chloride of zinc.

Of the antiseptics, properly so called, by far the most efficacious are carbolic acid, sulphurous acid, the sulpho-carbolates of zinc and copper, eucalyptus, thymol, and iodoform.

Carbolic acid is a powerful disinfectant and antiseptic, effectually destroying the germs which induce putrefaction, and arresting the process when it has set in. It is not a deodorizer, but unhappily substitutes one bad odor for another, and in this respect it is inferior to the other septicides. On account of its destructive action on all minute forms of organisms, which cannot exist in its presence, it has been employed with alleged remarkable success, by Professor Lister and others, for preventing the access of putrefactive fermentation in compound fractures and dislocations, lacerated wounds, amputations, excisions, and different kinds of abscesses, especially chronic. It should be remarked, however, that the solutions usually employed are entirely too weak to act as germicides, and that if the strength be increased the agent proves to be not only a direct irritant, but is also liable to excite alarming effects of narcotico-irritant poisoning, which generally terminate fatally. For these reasons carbolic acid is now employed less frequently than it was a few years ago, the agents with which it is being replaced being thymol and eucalyptus.

Sulphurous acid is one of the most valuable and powerful of the septicides, and possesses the advantage over most of the other agents of this class of being, at the same time, a deodorizer. The fluid acid of full strength may be applied to wounds and ulcers either by sponging or in the form of spray. It is superior to carbolic acid when added to moist, putrefying matter, as it not only destroys organic germs, but also the odor of the mephitic gases of decomposition, a property not possessed by the latter agent.

Sulpho-carbolates of zinc and copper have been employed in the treatment of wounds by Professor John Wood and others, in the proportion of three to five grains to the ounce of water. The solution may be applied by irrigation, or by patent lint covered with some impermeable material, as gutta-percha cloth. As direct antiseptics they are inferior to carbolic acid, sulphurous acid, and the metallic salts; but, as Mr. Sansom observes, their value lies in the protraction of their action, the carbolic acid being slowly liberated by the disintegrating action of the fluids on the salts.

Eucalyptus and thymol, like all aromatics, are excellent remedies for substituting a pleasant for an offensive odor, and for restraining putrefactive fermentation. They do not, moreover, irritate the tissues, nor do they produce toxic effects upon the system. As an antiseptic dressing, eucalyptus may be employed in the form of the oil or alcoholic tincture, while the best solution of thymol consists of one part of that substance to ten of alcohol, twenty of glycerine, and one thousand parts of water.

Iodoform is at present attracting no little attention as an antiseptic, especially in the hands of German surgeons. It may be sprinkled upon the wound, or the latter may be

enveloped in gauze impregnated with it. The pungent odor of the remedy may be corrected by the use of the Tonka bean, or by the addition of two parts of balsam of Peru, or of one-tenth of its weight of thymol, which do not appear to impair the efficiency of its action. Great care should be exercised in its employment in infants and in extensive wounds, since it has occasionally proved fatal, under these circumstances.

<center>SECT. XIII.—ESCHAROTICS.</center>

There is a class of operations which consists in destroying the affected tissues with caustics, consisting of the hot iron and of various escharotic substances. These procedures, however, once so much in vogue among surgeons, have become almost obsolete, although they are perhaps still too much practised in certain quarters, especially in France. At the present day they are restricted, in great measure, to affections of the neck and orifice of the uterus, superficial morbid growths, hemorrhoidal tumors, varicose veins of the extremities, specific ulcers, as chancroids, and malignant pustules, and bites of snakes and rabid animals.

When the hot iron is used for any of the purposes in question, it should be heated to a white heat, and retained in contact with the diseased parts sufficiently long to effect their destruction, their surface being previously thoroughly dried. In performing the operation, the surrounding structures should be carefully protected from injury, and in order to obtain the desired result it is frequently necessary to have two, three, or even four cauteries in readiness, so that, as one becomes cold, another may take its place. The eschar generally drops off at a period varying from six to eight days. The best apparatus for heating the iron is a little furnace charged with charcoal, the combustion being promoted with a pair of bellows. The

Fig. 191.
Different forms of Cauteries.

annexed sketch, fig. 191, conveys a good idea of the principal forms of iron in use at the present day. The conical-shaped instrument is well adapted for cauterizing narrow and deep-seated cavities, and the cylindrical one may also be used for this and similar purposes. The hatchet-shaped iron is well adapted for making a linear eschar, and the large round one for establishing a deep, permanent issue.

Many of the inconveniences attendant upon the use of the ordinary hot iron may be done away with by the employment of the *thermo-cautery* of Paquelin, represented in fig. 192. The platinum tip, *a*, which is the essential part of the contrivance, is first heated in the flame of an alcohol lamp, *b*, and then rendered incandescent by compressing the bulb, *c*, through which a steady stream of painter's benzine of 0.715 sp. gr. contained in the bottle, *d*, is carried to *a*. Unless great care be exercised the apparatus is liable to get out of order; hence it should be thoroughly cleaned every time it is used.

Hydrate of potassium, ethylate of sodium, the Vienna paste, chloride of zinc, bichloride of mercury, arsenic, ammonia, and certain acids, as the nitric, hydrochloric, and sulphuric, are powerful caustics, producing their peculiar effects more or less promptly, according to the length of time during which they are retained, and the strength in which they are used. As their application is generally attended with severe pain, it is proper that the patient be previously put under the full influence of an anæsthetic. Moreover, as some of the articles here specified have a tendency to diffuse themselves over the surrounding healthy surface, care should be taken to prevent this by placing a wall of simple cerate or collodion around the part to be cauterized.

Hydrate of potassium is a powerful escharotic, but as it is extremely painful and very tardy in its action, it is now seldom employed. The Vienna paste, composed, as already stated, of equal parts of quicklime and hydrate of potassium, although also productive of severe suffering, does its work much more rapidly—generally in from ten to fifteen minutes—and is, therefore, usually preferred. Hydrate of potassium is often used most conveniently in the form of small sticks.

The *ethylate of sodium* which is converted into caustic soda when brought in contact with moist tissues, is a gradual but potent agent, which I have found to be very useful in

cicatrizing epithelioma, rodent ulcer, and other malignant affections in which the use of the knife is contraindicated. If the pain produced by its application should be severe, it may be checked by dropping chloroform upon the part, which converts the agent into an inert ether and chloride salt.

Fig. 192.

Thermo-cautery of Paquelin.

Chloride of zinc is usually mixed with farina, forming thus what is called the phagedenic paste of Canquoin, of which there are three strengths, known as number one, two, and three; the first consisting of one drachm of the salt to double that quantity of farina, the proportions of the second being as one to three, and of the third as one to four, the latter being of course much the weaker. The preparations act with great efficiency, but are productive of excessive pain.

Bichloride of mercury, in the proportion of three parts to one of powdered opium, with the addition of a sufficient quantity of sulphuric acid to convert it into a paste of the consistence of tar, makes a powerful escharotic; but, owing to the excessive pain which it causes, and the risk of its inducing salivation, it is now rarely used. A similar objection is applicable to the caustic mixture, formed of equal parts of white arsenic and sulphur, formerly so much in vogue. A decided escharotic effect may speedily be produced by the use of equal parts of ammonia and lard.

A very destructive escharotic, admirably adapted for the removal of epithelial growths, may be prepared with fifteen grains of white *arsenic*, seventy-five of cinnabar, and thirty-five of burnt sponge, made into a thick paste with a few drops of water. This constitutes what is called Manec's paste, and is applied in the form of a thin layer to the surface of the affected part, previously well cleansed in order to promote its effects. The great objection to this remedy is the excessive pain it produces and its liability to cause vomiting, depending, doubtless, upon the absorption of some of the arsenic. Generally, also, its application is followed by deep discoloration and severe swelling. For these various reasons it should be employed with great caution, or be replaced by Esmarch's powder, which is composed of one part each of arsenious acid and muriate of morphia, eight parts of calomel, and forty-eight parts of powdered gum arabic.

The *carbo-sulphuric* paste, as it is termed, is prepared by mixing powdered charcoal and sulphuric acid in sufficient quantities to form a semisolid mass. It is a powerful escharotic, formerly much employed by Ricord in the treatment of chancroid. Applied in the form of a thin layer, it rapidly destroys the tissues, and soon dries into a thick, adherent crust, which usually drops off in from six to eight days, leaving a clean sore. The only objection to this caustic is that it causes excessive pain.

The stronger *acids*, as the nitric, hydrochloric, and sulphuric, produce an instantaneous escharotic effect when applied to a denuded surface; hence they are often used for cau-

terizing inoculated wounds and destroying the edges of ulcers. Of all the acid preparations, however, the best and most reliable is the *acid nitrate of mercury*. The formula which I employ is that usually known in this country as Bennet's. It is prepared by dissolving, with the aid of heat, 100 parts of mercury in 200 parts of nitric acid, and evaporating the solution to 225 parts. The application produces a white eschar, which is detached, piecemeal, from the third to the tenth day. *Chromic acid* also deserves favorable mention; its application, which causes but little pain, is particularly valuable in cases of warty excrescences and of recent chancroids. When merely a superficial caustic effect is desired, *carbolic acid* will be found highly serviceable: it is particularly beneficial in unhealthy, suppurating wounds, in gangrenous ulcers, and in open carcinomas attended with foul discharges, the odor of which it promptly and effectually arrests. It may be used pure, or variously diluted with glycerine, according to the intention of the application. Whatever article be employed, the utmost care must be taken to prevent its diffusion over the surrounding healthy tissues, otherwise the effects may be most unfortunate. Cauterization with *caustic arrows* is a method of destroying the tissues in carcinomatous and other growths originally employed, in 1858, by Maisonneuve, of Paris. It is particularly applicable to carcinoma of the breast and uterus, but is also practised, especially by its inventor, in epithelioma of the lip, tongue, tonsils, palate, anus, and rectum. The arrows are flattened, wedge-shaped pencils, of variable sizes, cut from a thin cake of dough, composed of three parts of wheat flour with one of chloride of zinc, as much water being added as may be necessary to give the mass proper consistence. When the arrows are dried, they may be kept a long time without losing any of their properties. To facilitate their insertion, a small preliminary incision in the skin is required. The number employed varies, of course, with the amount of substance to be destroyed. As the attendant pain is very great, the patient should always have the benefit of a full anæsthetic. The necrosed tissues gradually become hard, black, and insensible, and drop off at a period varying from six to twelve days, leaving a raw surface which, under the influence of mild emollient dressings, is soon covered with healthy granulations. The advantages claimed for this method of cauterization are that it is entirely free from hemorrhage, that it may be employed in situations inaccessible by the knife, and that it is rarely followed by erysipelas, pyemia, or violent fever. These advan-

Fig. 193.　　　　　　　　Fig. 194.

Fig. 193.—Maisonneuve's Plan of Circular Cauterization by Wedge-Shaped Pieces of Caustic.

Fig. 194.—Maisonneuve's Plan of Parallel Cauterization by Lancet-Shaped Pieces of Caustic.

tages, however, have been greatly overrated. Copious bleeding sometimes accompanies, or succeeds, the application; nor are the other ill effects as uncommon as the French surgeon asserts. The annexed cuts, figs. 193 and 194, afford a good idea of the shape of the arrows and the manner in which they are inserted.

Perchloride of iron is a very mild, but in many cases a very efficient caustic, and at the same time a powerful hemostatic, producing rapid contraction of the vessels, and checking hemorrhage at once with very little pain. It is particularly adapted to carcinomatous sores and old ulcers attended with exuberant and flabby granulations. It may be applied either in substance or in saturated solution. A few drops may occasionally be advantageously injected into the tissues at the periphery of a fungating and bleeding tumor.

SECT. XIV.—MASSAGE.

Massage, in its original sense, implies kneading; but, as at present used, it has a much wider signification, comprising all kinds of passive manipulation, as friction, shampooing, percussion, and rolling of the soft parts. As a therapeutic agent, it has been in vogue, in some form or other, from time immemorial, although it has only been, of late years, chiefly through the influence of the labors and writings of some of the Danish physicians, that it has attracted much attention. Its principal claim to notice is in connection with the

treatment of subacute and chronic affections of the joints, in which in the hands of the skilful operator, it is frequently productive of very marked benefit. It may also be advantageously used in subacute and chronic cellulitis, attended with deposits of serum and lymph, especially the latter, and consequent induration of the soft parts. Massage has also been found serviceable under similar circumstances in affections of the lymphatic glands.

The beneficial effects of massage are, doubtless, due to the influence which it exerts upon the lymphatic vessels, and possibly, also, upon the veins, stimulating them to augmented action, and thus inducing them to remove inflammatory deposits. These vessels during the progress of disease are often so thoroughly choked up by plasma and other material as to deprive them completely of their power as absorbing agents. They are, indeed, not only compressed by, but frequently even filled with, these substances. The object in the employment of massage is to increase the activity of the lymphatic vessels, so that, by the ridding of them of these deposits, they may be enabled to resume their normal condition, and at the same time assist in restoring the structures around them to their natural size, shape, and pliancy. What the husbandman does for his grain when choked by weeds, massage does through the agency of the absorbent vessels for the affected structures.

Massage, in whatever form employed, may be used dry, or with the aid of various lotions, embrocations, liniments, or unguents, according to the fancy or caprice of the operator, or the special indications of the case. Dry massage is particularly applicable in chronic affections, whereas the other form is generally best adapted to the subacute. There are of course many exceptions ; and, to render the remedy effectual in every case, it must be frequently varied.

The treatment by massage is wholly inapplicable during the height of inflammatory action, or during the existence of suppuration. The parts covered with hair should be well shaved before the operation is begun, otherwise irritation will be likely to be set up in the piliferous bulbs, so as to interfere more or less seriously with the result. The period during which the manipulations should be continued must vary, according to circumstances, from a few minutes to half an hour or more.

In regard to friction, there are two principal directions in which it may be employed, the transverse and vertical, the former being more especially adapted to the removal of deep-seated, and the latter to superficial, affections and deposits. To render the rubbing, in whatever direction made, effective, both hands previously oiled are generally required. Kneading, rolling, and percussing the structures are often important auxiliary measures, powerfully aiding in the removal of plastic material. In the treatment of stiff joints, passive motion should always be performed immediately after the massage, and the parts, if need be, should be covered in the intervals of the operation with compresses wet with cold water, or some astringent and sorbefacient lotion. The absorption of effused fluids is often powerfully promoted by combining massage with irritating embrocations, liniments, or unguents.

Muscle-beating is a peculiar form of massage introduced by Klemm, of Riga. It is performed with an instrument called the muscle-beater, consisting of three elastic tubes, each about the size of a finger, and fastened together near the handle to which they are attached. The length of the tubes varies according to the object it is desired to secure. The skin should be protected with a thin cloth covering, and the force used in the beating proportioned to the impressibility of the patient. The application which should be interrupted by short pauses, should not be too long continued, lest undue irritation be excited. Muscle-beating may be advantageously practised in various chronic affections, attended with stiffness or partial ankylosis, sprains, rheumatism, dislocations, fractures, spinal weakness, and locomotor ataxia. With a little instruction in the use of the instrument, the patient can perform the manipulations as well as the professional attendant. An elastic hammer having a surface one inch and a half in diameter would answer quite as well as Klemm's elastic tubes ; and, in their absence, effective muscle-beating could readily be performed with the thick part of the palm of the hand.

SECT. XV.—DRESSING.

The art of dressing, humble though it be, must not be despised by the surgeon ; since, in many situations, both in private and hospital practice, it must necessarily form a part of his daily routine duties. There is, indeed, great reason to believe that this matter is

too much neglected by practitioners, and that it is too frequently delegated to ignorant, careless, and unscrupulous nurses, and to the so-called dressers, who are often not a whit more enlightened, or more con-
scientious.

Fig. 195.

The most important appliances used in dressing are forceps, scissors, and syringes, sponges, lint, pledgets, tents, adhesive plaster, bandages, cataplasms, and unguents.

Dressing Forceps.

The *dressing forceps*, fig. 195, differs from the ordinary dissecting forceps in having ring handles, and cross blades, terminating each in a rounded, spoon-shaped extremity, supplied internally with serrated edges, to adapt it the better for seizing and holding such substances as may require removal. They are light and slender, and from four and a half to five inches in length. When not at hand, the ordinary dissecting forceps may advantageously be used as a substitute.

The best *scissors*, for dissecting purposes, are the ordinary straight, pocket-case instrument, which may be used either for cutting adhesive strips and bandages, or, if necessary, for paring the edges of ulcers, or for removing redundant granulations. Scissors curved on the edge or flat are sometimes very convenient.

The *sponges* used in dressing should be very soft and clean, and the same articles should never be employed upon different persons, especially if affected with open ulcers, as the discharges might thus be made the vehicle of propagating disease, as, for instance, in chancroid, gonorrhœa, erysipelas, malignant pustule, pyemia, and hospital gangrene. In all such cases they should be destroyed as soon as the dressing is completed, or thoroughly washed in water, and then soaked in a solution of chlorinated sodium or carbolic acid.

No sore should ever be wiped; instead of this, the water should be pressed upon it from a sponge held some distance from its surface, which will usually effectually wash away any secretions that may be in contact with it. Adherent lymph, charpie, or unguent may be picked away with the forceps. The surface around, however, may be gently sponged, if soiled; otherwise it may be wiped with a soft, dry cloth. The water, which may be tepid, cool, or cold, according to circumstances, is received into a suitable basin, placed beneath the affected parts. The old dressings are put into a separate vessel, and promptly removed from the patient's apartment. Fetor is allayed by the free use of deodorizers, sprinkled both upon the body and bedclothes, as well as about the room.

Lint is a soft, fleecy substance, consisting either of prepared cotton or scraped linen, or, what is preferable, the ravellings of linen, as those of an old napkin, sheet, or pillow-case, each thread being picked out separately. The article generally employed in this country is patent lint, which is kept in rolls in the shops, and makes an excellent dressing, although not equal to linen ravellings, or the charpie of the French surgeons: one surface is glazed, the other smooth. The objection to it is that it is not sufficiently porous to admit of the free escape of the secretions of the parts to which it is applied, and, consequently, also, that it keeps them too warm.

A very excellent, cheap, and convenient article for dressing wounds and ulcers may be prepared by folding a piece of old muslin, until it forms a body from a quarter of an inch to half an inch in thickness, and then punching numerous holes into it, giving it thus a sieve-like appearance. It is very light and airy, and, while it absorbs moisture, it also admits of ready drainage. It forms a good substitute for patent lint, and is much used, both in private and hospital practice, in cases where the other is not applicable. It is known as perforated muslin.

Oakum, consisting of picked ship rope, was extensively used during the late war as a dressing in gunshot and other wounds, attention having been specially directed to it in connection with this subject by Professor Lewis A. Sayre. It combines cheapness with softness, is easily adapted to the affected surface, and, being impregnated with tar, is an excellent antiseptic and deodorizer. As an absorbent, however, it is far inferior to patent lint, charpie, and tow.

Instead of oakum, *tenax* is now much employed as a dressing for wounds. It is an absorbent and antiseptic substance, which possesses the tarry odor of oakum, but is much softer and lighter, and readily imbibes and retains the secretions of the affected surface, at the same time that it effectually prevents any unpleasant emanations. Its cheapness is an additional reason for its employment.

Tow has long been employed as an absorbent of persistent discharges in wounds and ulcers, and, if properly picked and carded, is equal to any substance that can be applied for the purpose. The ordinary article contains so much hard, sharp matter as to be unfit for use.

Cotton-wool, saturated with water, tepid, warm, or cold, may often be advantageously employed for cleansing wounds, as it is less irritating, when applied directly to the raw surface, than sponge. It may also be conveniently used as a medium of medicated dressings.

Spongiopiline is a valuable dressing. It is a soft, light, porous fabric, made of sponge and muslin, in sheets from half an inch to an inch in thickness, covered with a glazing of India-rubber, to fit it the better for retaining water and preventing evaporation. It is more particularly adapted as a dressing to inflamed surfaces unattended with breach continuity.

Paper, prepared in various ways, forms a very good cheap substitute for patent lint as a surgical dressing. Professor Agnew, some years ago, recommended the use of a very thick, soft paper, made of old rags, deodorized with chloride of lime. One surface is velvety, and the other dense and leathery.

Sometimes the lint is arranged in the form of a *compress*, pledget, ball, roll, tampon, tent, or pellet, thus adapting it the more conveniently to particular purposes. Thus, a compress consisting of a strip of folded muslin, lint, or linen, may be employed for pressing together the sides of a deep abscess, or a number of pieces may be piled upon each other, so as to form a graduated compress, which is often advantageously used for compressing a bleeding vessel, as the brachial artery where it runs along the inner edge of the flexor muscle. The *pledget* is a strip of patent lint, usually spread with cerate, for protecting the surface of a granulating ulcer. Balls, rolls, and tampons are simply masses of soft substance, as charpie, lint, or cotton, arranged so as to adapt them to particular cavities, as the uterus, the nose, or a deep wound, either with a view of arresting hemorrhage, or for absorbing pus and other fluids. The *tent* consists of a piece of linen, muslin, or patent lint, twisted on its axis, slender, and usually several inches in length, its object being the prevention of the reunion of the sides of the incisions made in evacuating abscesses, and in laying open sinuses, as in the operation for anal fistule. Tents are sometimes prepared with wax, generally of a conical shape, and employed as dilators. Finally, the *pellet* is a ball, roll, or mass of soft tissue, inclosed in a strip of soft cloth, firmly tied; it may be used for the same purposes as the tampon, of which, in fact, it is

Fig. 196.

Drainage-tube and Forked Probe.

merely a variety. When intended for the nose, uterus, or rectum, a stout thread or piece of twine may be tied to it in order to facilitate its removal. Dr. Addinell Hewson employs ordinary paper, similar to that used for printing purposes. When the object is to confine heat and moisture, as in the application of a poultice or warm water-dressing, the best article is oiled silk, or when this cannot be obtained, oiled paper or impervious lint.

The *drainage-tube*, as a means of favoring the discharge of matter from abscesses and sinuses, especially when large, devious, or deep seated, is not, as has been generally supposed, a recent invention, but of ancient date, extending back to the time of Ambrose Paré, by whom it is repeatedly mentioned in his great work on surgery in connection with gunshot wounds and injuries of the chest. He speaks of it as preferable, in many cases, to tents, in freeing wounds and ulcers of irritating matter, and promoting the formation of healthy granulations. He used lead and various other materials in its composition, with apertures near its extremities. The surgeons of Philip II., king of Spain, employed drainage-tubes in the treatment of that monarch's case to drain a large abscess with which he was afflicted. To Chassaignac, however, is unquestionably due the credit of calling the attention of the profession to the subject in modern times, and of pointing out, in clear and distinct terms, the class of cases in which the drainage-tube can be used to the best advantage.

Drainage-tubes are composed of various materials, as soft rubber, fig. 196, decalcified bone, lead, or silver; they are cylindrical in shape, of variable length and diameter, and

perforated with numerous apertures, to admit of the free ingress of matter in every direction, at the sides as well as at the extremities. Whatever the substance may be, it should be smooth, light, and non-irritant, and the openings must be sufficiently large to prevent them from becoming clogged. No sulphur should enter its constitution, as this would impart an offensive odor to the secretions.

The late Dr. H. Lenox Hodge invented what he called a drainage-probe, which he considered preferable to the ordinary drainage-tube. It is made of flexible silver, and terminates at each end in an olive-shaped bulb.

Poultices form an important element in a great variety of dressings, but as this subject has already been fully described, I shall here only add, that when they are selected for this purpose, they should be used with special reference to the comfort of the parts, care being taken that they do not oppress by their weight, or irritate by their long retention and the stimulating character of their ingredients. The mode of employing water-dressings has also been so fully considered in another part of the work as to render any further remarks regarding them here unnecessary.

Unguents, ointments, or salves of various kinds are employed as dressings in ulcers and other open surfaces; much has been said and written upon the subject, especially of late years, and attempts have been made to discard these substances altogether from practice. Still, notwithstanding all this, unguents hold a prominent place in the affection of many practitioners, as well as in that of the common people, and it would be difficult, I am sure, always to dispense with their use. Prejudice, I imagine, has had much to do in proscribing this class of remedies. No one will pretend to assert that rancid ointments do not act as irritants; this, however, is not the fault of the article, but simply of its misuse. Prepared and employed for the occasion, experience shows that the application of unguents is often attended with the most salutary effects, admirably protecting granulating surfaces, and rapidly promoting cicatrization. As a general rule, I have found that all the officinal medicated ointments are much too strong, requiring to be diluted from one-half to seven-eighths. Petroleum has, in great degree, taken the place of most of the older simple ointments, inasmuch as it is less liable to become rancid and offensive. Cosmoline or vaseline is one of the most approved preparations of this kind, and another, recently introduced, is fossiline, a hydrocarbon jelly of superior consistence and smoothness.

Glycerine, either alone or variously combined, forms an excellent dressing in granulating wounds and ulcers, in different eruptive diseases of the skin, in ulceration of the uterus, and in certain forms of deafness, especially when dependent upon dryness of the drum of the ear, or the presence of indurated wax. Although its utility has been greatly exaggerated in these and other affections, it is unquestionably a valuable addition to the domain of modern surgery. It is best applied upon soft cotton or coarse lint, previously well pressed out of tepid water. Its effect, thus employed, is to exclude the air, to keep the sore moist and clean, and to favor capillary drainage by osmosis, thereby depleting the tissues, provoking a copious discharge of serum, lessening suppuration, and promoting cicatrization. Glycerine has great affinity for water, and a bit of cotton saturated with it will retain its humidity for days, even if continually exposed to the air. It has the additional advantage of being perfectly bland, non-adherent, and easily removable by ablution.

Glycerine may often be advantageously combined with other articles, as tannic acid, opium, soda, and the mineral acids, according to the indications of the case.

Dr. Hewson has extensively employed *dry earth* as a dressing in burns and scalds, ulcers, wounds, both recent and suppurating, and in compound dislocations and fractures, with the effect, not only of excluding the air and preventing the offensive odor so common in such cases, but also of allaying pain and hastening the healing process. Dr. Darby, of Boston, has been equally successful in the management of these affections with the use of carbolized dry earth and carbolized bran.

The earth, as used by Dr. Hewson in his dressing, is always taken at a depth of from two to three feet below the surface, and is kept in large dry lumps until needed, when it is pulverized, sifted, and applied, either dry, as in an open surface, or converted into a thick paste with water when employed as a sorbefacient, as in the case of sprains, contusions, or tumors, a layer half an inch thick, confined in muslin, and covered with a suitable bandge, generally sufficing. Or, instead of this, the paste may be spread all over the affected parts, or applied on strips. The dressing is renewed as soon as it becomes offensive or ceases to produce the desired effect. In most cases it is necessary to effect the change on a sound surface by the end of the third day, and, on an open one, as often as every twenty-four hours.

Compressed sponge as a remedial agent, in the form of conical tents, as represented in fig. 197, or of flattened plates, is particularly useful in the treatment of sinuses and fistules,

Fig. 197.

Sponge-Tent
Holder.

strictures of the rectum, contraction of the canal of the neck of the uterus, chronic enlargement of the lymphatic glands, venereal buboes, and chronic swelling and induration of the testicle and mammary gland. It may also be advantageously employed for dilating the female urethra, and the wound made in the operation for the relief of atresia of the vagina and anus. The late Dr. J. P. Bachelder, who published an elaborate article on this mode of treatment in the New York Journal of Medicine for May, 1859, asserts that he had repeatedly employed it with great benefit in the suppression and arrest of various morbid growths, both benign and malignant, and similar testimony is borne by other observers.

The sponge, which should be soft, elastic, and well cleaned but not bleached, may be compressed with any heavy weight, or, what is better, a special apparatus, and, when perfectly dry, cut into strips of appropriate size and shape. When the object is to compress a swollen and indurated organ, as the breast or testicle, the piece should be sufficiently large to embrace the whole of the affected structures, to which it should be secured with a suitable bandage, the dressing being kept constantly wet with cold water, to promote the expansion of the sponge. Change or substitution is affected whenever pain, discharge, or fetor renders it necessary.

When sponge is intended to be used for sinuses or mucous outlets, it should be formed into tents by cutting it into conical pieces, slightly tapering at the end, from one to two inches and a half in length, traversed by a wire in the long axis, saturated with thick mucilage of gum arabic, and tightly wrapped around with small twine, beginning at the narrow extremity, and gradually terminating at the larger. When perfectly dry, the wire and cord are removed, and the surface smoothed with fine sand-paper. Daily substitution is effected, as the sponge soon becomes filthy, fetid, and worthless, not only exciting irritation and discharge, but endangering the system by pyemia. These effects may, it is true, be in some degree, counteracted by the addition of a little carbolized glycerine, but the objection to this is that it sometimes interferes with the expansion of the sponge.

The period during which the application should be continued must vary with the nature of the case. Great dilatation of a sinus or natural canal, as the urethra or vagina, may usually be effected in a very short time, and an enlarged breast or testicle may often be astonishingly reduced in a few days.

The stem of the *sea tangle*—the *laminaria digitata* of botanists—is another article that may be advantageously used for dilating purposes. The only objection to it is the presence in it of a certain amount of iodine, sodium, and potassium, which causes it to be more or less irritating to the parts with which it is brought in contact. Previous

Fig. 198.
Greenhalgh's Sea-tangle Tent.

thorough maceration in simple water, however, will readily deprive it of this quality. Its extraordinary expansion under the influence of the warmth and moisture of the living tissues admirably fits it as an agent for rapid dilatation. Its surface, which is naturally rough, should be well smoothed before it is introduced. Dr. Greenhalgh uses a tubular sea-tangle tent, fig. 198, as it expands more rapidly than the solid one. Tupelo tents, to which attention has been called by Dr. Leopold Landall, are prepared of the root and stem of the nyssa aquatica, and form excellent dilators in contracted conditions of the vagina, uterus, and other mucous canals. Their superiority over sea tangle and sponge-tents consists in their more rapid and uniform expansion.

Whatever the dressings may be, they should be carefully confined by means of a bandage, evenly and lightly applied, so as to afford the requisite support, and no more. In most situations, this may readily be done with the common roller; but in certain regions, as the groin, perineum, anus, and head, particular contrivances may be necessary, as the spica, the T bandage, and the four-tailed bandage. For retaining dressings upon the scrotum and mammary gland the suspensory bandage will be found most convenient. Adhesive strips also answer a good purpose.

For confining the heat and moisture of poultices and warm water-dressings *oiled silk* is usually employed, although oiled or waxed paper answers quite as well, and, as it is much cheaper than oiled silk, it is entitled to preference for general use. To maintain cleanliness, frequent substitution should be effected.

A very cheap and convenient dressing made of thick porous paper, rendered water-tight on one surface with a film of India-rubber, was introduced at the Pennsylvania Hospital, a few years ago by Professor Agnew, and has been found very serviceable as an application in wounds and other affections, as it not only readily absorbs their secretions, but prevents the evaporation of water and other fluids.

The adjoining cut, fig. 199, represents the "ward carriage," as it is called, devised by Dr. Thomas G. Morton, of this city, and used with such signal benefit since 1866 at the Pennsylvania Hospital. Its arrangements could not possibly be more perfect, more compact, or better adapted to the objects for which it was constructed. The carriage is made of oak, with gutta-percha tires, and is so light as to be easily pushed noiselessly across the floor from bed to bed. It is provided with a heating apparatus, a long gutta-percha tube for cleans-

Fig. 199.

Morton's Ward Carriage.

ing wounds and ulcers, and with compartments for the accommodation of jars, bottles, sponges, and, in short, all the means and appliances necessary for dressing purposes in a large hospital.
SECT. XVI.—BANDAGING.

Bandages are substances employed for retaining dressings in cases of wounds, ulcers, abscesses, fractures, dislocations, and other affections, as well as with a view to their direct curative effects, which, as will be shown by and by, are probably much greater than they are generally supposed to be. They vary much in shape and size, and also in regard to the materials of which they are composed, and the object which they are designed to fulfil. A vast number of bandages have been described in certain modern works, especially those on minor surgery, much ingenuity, and, according to my belief, much time having been wasted, in trying to adapt them to every part and region of the body, and to every circumstance, however insignificant, to which such contrivances can possibly be applied. By running into these extremes, the art of bandaging has been greatly complicated, and much injury inflicted upon a department of surgery, which, if properly administered, is capable of conferring immense benefit in almost every form of accident and disease affecting the external parts of the body. The ancient surgeons racked their brains to invent names for designating bandages, and the claims of not a few of them to distinction were based almost exclusively upon such absurd and puerile pursuits. If a man was so fortunate as to devise an apparatus for expelling peccant humors, for retaining a cataplasm upon the scalp, or for supporting a diseased breast, the height of his ambition was generally amply gratified. It is to be feared that these employments have had too many imitators in modern times.

The more simple a bandage is, the more likely will it be, if judiciously used, to answer the purpose for which it is intended, all complicated contrivances of this kind being objectionable on account of the difficulty of applying them, the ease with which they become deranged, and the trouble and vexation of changing them, the attempts to do so being frequently attended with serious inconvenience and pain to the patient, and perhaps great detriment to the parts affected. In general, the single-headed roller is all that can be required in almost any case; occasionally the strip-bandage, commonly known as the bandage of Scultetus, represented in fig. 200, may advantageously be employed, especially in compound fractures and dislocations. The many-tailed bandage ought, on the contrary, to be discarded from practice, as inconvenient and useless. It consists, as the name indicates, of a number of transverse slips, of the same width but unequal length,

stitched to a longitudinal portion, and was formerly much employed in fractures of the leg.

Bandages are composed of various materials; commonly of muslin, bleached or unbleached, of calico, or of linen, the only objection to the latter being its expense. Occasionally they are made of flannel, especially when it is desirable to protect the parts from cold, as in œdema of the extremities, and in the swelling attendant upon a gouty or rheumatic state of a joint, in persons of an unhealthy, broken constitution, who are commonly so extremely susceptible of atmospheric vicissitudes. In general, muslin will be found to answer every purpose, being both cheap and easily procured; it should be soft, firm, smooth, strong, and not too yielding, divested of selvage and seam, and washed before it is applied. Calico is not a good material for bandages, as it is usually too light and flimsy. The gum-elastic bandage is of great service in the treatment of old ulcers, in eczema of the lower extremities, in chronic affections of the joints, in elephantiasis, in chronic œdema, and in varicose conditions of the veins, and deserves more attention than it has hitherto received. Dr. Henry A. Martin, of Boston, is entitled to much praise for the pains he has taken to introduce this invaluable agent to the notice of the profession. The use of Esmarch's bandage in preventing hemorrhage in amputations and in the cure of aneurism is too well known to need comment.
Fig. 200.

Bandage of Scultetus.

The length and width of a bandage are of course subject to much diversity, depending upon the shape and size of the part to which it is intended to be applied. Hence, while in one case it need hardly be half an inch in width, and not more than a foot in length, in another it may require a width of two, three, or even six inches, as in injuries of the chest, and a length of many yards. Muslin is usually torn into strips of the requisite size, whereas linen, being much stronger, is best shaped with the scissors. The ravellings being picked away, each piece is rolled into a firm cylinder, and put away for use, so that it may be ready for any emergency that may arise. The winding may be effected either by hand, the cloth being held upon the front of the thigh, or by appropriate machinery, such as is to be found in the office of every practitioner, and of which illustrations may be seen in most of the works on minor surgery. However effected, it should be done with great care, since no one can possibly apply a bandage well that has been wound in a loose and slovenly manner.

When intended to be used upon an extremity, the rule is always to begin at the distal portion of the limb, and to proceed from thence upwards some distance beyond the seat of the disease or injury. The end of the bandage being slightly unfolded, is held firmly upon the part with one hand, while the cylinder is carried round the limb with the other, and thus the application is continued by circular and reversed turns, as they are named, until the object has been completed, the fingers being pressed upon each reverse to flatten and equalize it, as in fig. 201. If the bandage were put on spirally, it could not maintain itself upon the limb for any length of time; and, what is worse, the compression would be so unequal as to cause severe suffering and perhaps even mortification. The application, then, must be made circularly, and care taken that each turn of the roller be reversed, so that the inner surface shall be the outer, and the upper edge the lower, the pressure being uniform throughout, or not greater at one point than at another, as in fig. 202.

The evil effects of unequal compression by the bandage are well illustrated in fig. 203, copied from John Bell; it also shows how important it is always to begin the application of the bandage at the distal extremity of a limb, and not above the wrist or ankle, as happened in the case so graphically described by the celebrated Scotch surgeon. In all cases of severe injury or disease, with a tendency to swelling and to the extension of the

morbid action, due allowance must be made for the inflammatory effusions that will necessarily occur. Hence, too much care cannot be taken both in applying the bandage and in watching its effects afterwards. For want of this precaution many a limb has been destroyed, and the reputation of many a practitioner irretrievably ruined.

Fig. 201.　　　　　　　　　　　　　　　　　　　Fig. 202.

Mode of Applying the Roller by Circular and
Reversed Turns.
Appearance of the Bandage after it has been
Applied.

Some surgeons employ the double-headed roller; but I have never had occasion to use it, and am satisfied that there are few cases, if any, in which it may not be advantageously replaced by the single-headed. The double-headed bandage is considered as being particularly serviceable in the treatment of wounds penetrating deep among the muscles, where it is of paramount importance to effect accurate apposition of the deep as well as of the superficial sides of the solution of continuity; but even here no indication is presented that cannot be readily fulfilled with the compress and single-headed roller. In my own practice I have certainly never been at a loss in this respect.

The bandage of Scultetus, represented in fig. 200, consists of a number of strips, generally from ten to twenty, or of pieces of an ordinary roller, of equal or unequal length and breadth, according to the intentions of the surgeon. They are arranged in such a manner as that, when applied, each succeeding one shall overlap from one-third to one-half of the preceding one, the compression being made in the same gentle, uniform manner as in the employment of the ordinary roller. This form of bandage is peculiarly useful in the treatment of compound fractures and dislocations, in connection with which it will frequently be mentioned.

Bandages are sometimes applied wet; but in doing this much vigilance must be exercised, lest, shrinking too much as they dry, they produce a greater degree of compression than is compatible with the comfort and safety of the parts. What is called the starched bandage, an excellent modern device, will receive particular attention in connection with the treatment of fractures of the extremities, to which it is more especially adapted. When it becomes dry, it forms a stiff, firm, immovable case, well adapted to maintain the ends of a broken bone in contact with each other. Amidon, gum-shellac, plaster of Paris, and kindred articles may be used for the same purpose, the bandage being wet with them, and immediately applied to the affected limb.

The bandage, viewed as a therapeutic agent, has been too much neglected by modern practitioners. No one who has properly used it, or who is capable of properly applying it, can, for a moment, doubt its great utility; my experience with it for the last fifty-five years amply attests this fact; still, it is necessary that we should temper our enthusiasm, and that we should not allow ourselves to be betrayed into a species of hobbyism, calculated to mislead the judgment, and to bring surgery into discredit. Employed indiscriminately, it cannot fail, in many cases, to cause serious mischief, and to be followed by chagrin and disappointment. When the hand of a master is not present to direct and guide our practice, the result may frequently be most disastrous both to the patient and the surgeon. The evil effects of bandages, in their aggregate capacity, are hardly less serious than those of mercury, the lancet, and other potent remedies; or, if they are, it is only because they are less frequently employed. Numerous instances have come to my knowledge, where limbs, and even life, were the forfeit of their injudicious use.

Fig. 203.

Gangrene from Strangulation of an Injured Limb by Injudicious Bandaging.

It is not difficult to perceive how the bandage acts in producing its salutary effects. In fractures and dislocations, as well as in large wounds, it powerfully controls muscular contraction, and at the same time prevents tumefaction, by giving tone and support to the capillary and other vessels. Its influence as a sorbefacient is evinced in the rapid abatement of the swelling which so often follows compression by the bandage in erysipelas, œdema, and various kinds of injuries; or, more strikingly still, in orchitis, when, after the subsidence of the more active disease, the testicle is strapped with adhesive plaster, which is but another form of bandage. Here in a short time, ordinarily in less than twenty-four hours, the swelling usually so far disappears as to allow the organ to slip out of its artificial case; or, at all events, to such an extent as to require renewal of the dressing. The general effect of the bandage would thus seem to be somewhat similar to that of mercury, controlling capillary action, and promoting the absorption of effused fluids; but it has the additional advantage, and no trifling one it is, that it supports the muscles and prevents spasm, as is so remarkably evinced in fractures and in the stump after amputation.

Of the extent to which bandaging may be carried, a good idea may be formed from the frequent allusion that will be made to it in different parts of this work; it will suffice here to observe that it is applicable, as a general rule, to the treatment of all classes of wounds, from the most simple to the most severe, to fractures and dislocations, ulcers, abscesses, erysipelas, whitlow, orchitis, chronic inflammation of the superficial veins, and to nearly all affections of the limbs in which there is an effusion of serum, or serum and plasma.

A bandage, once applied to an open wound, especially if there be much discharge, should never be used a second time. However carefully washed, it is very difficult, if not impossible, to remove all the matter, and hence it may readily become a source of infection, causing erysipelas, pyemia, hospital gangrene, and other bad effects. The danger will be particularly great in a recent wound, in a person laboring under severe shock or loss of blood. Even the act of washing a dirty, filthy bandage is not always devoid of danger.

CHAPTER XV.

OPERATIVE SURGERY.

OPERATIVE SURGERY has too often been regarded as an opprobrium of the healing art. This opinion, as foolish as it is unfounded, is not peculiar to the public, who, in matters of this kind, are generally but poor judges, but has frequently been advanced even by medical men. That this department of surgery is often abused cannot be doubted ; but does it thence follow that it is a disgrace to the profession and an injury to the community ? Such a view would be absurd, because it would be utterly irreconcilable with the dictates of common sense and the results of daily experience. So long as the human body is liable to accidents, and so long as nature is incapable of arresting, by her own efforts, the various morbid processes which she herself institutes, so long will practitioners be compelled to invoke the aid, and, I may add, the blessings, of operative surgery. Is it a disgrace to amputate a leg for a mortification of the foot, to extirpate a testicle that has been destroyed by cystic disease, to divide the stricture in strangulation of the bowel, to remove a stone from the bladder, to extract a cataract, or to trephine the skull in a punctured fracture ? Surely, no one will doubt that in these, and a hundred other instances, our object can only be attained by an operation. Medicine, under such circumstances, however judiciously administered, is not only utterly futile, but is always ready to avail itself of the aid of surgery. Its empire is temporarily suspended, and it only resumes its legitimate functions after the use of the knife. It is true beyond doubt, and it is fortunate that it is so, that, in the hands of judicious and enlightened practitioners, a resort to instruments is much less frequent now than it was even ten years ago ; many limbs which would formerly have been subjected to amputation are now easily saved, and many diseases which were once regarded as utterly hopeless now readily yield under the influence of our therapeutic efforts.

Operative surgery, as practised at the present day, is entitled to the highest respect and admiration of the profession, and the most profound gratitude of mankind. It has attained, if not its finality, certainly a wonderful degree of perfection ; it has emerged out of chaos into order, and out of darkness into light ; it has laid aside its farrago of instruments, and its fondness for blood and torture ; in a word, it has assumed the fair and stately proportions of an exact science ; and little remains to be done, in order to place it upon a firm and immutable basis, beyond its efforts to determine the best plans by which it seeks to accomplish its various purposes. Within the last twenty-five years it has literally invaded every organ and region of the body, and achieved feats of a character evincive of the highest daring, of the most varied knowledge, and of the most marvellous dexterity. Once regarded as a disgrace, it can be regarded so now only when it is practised for base and selfish ends ; not when it interposes its humane and beneficent resources for the purpose of removing disease, prolonging life, and averting death.

Qualifications of a Surgeon.—The performance of operations presupposes the possessions of certain qualities on the part of the surgeon. It is not every man that can become an operator, even presuming that he has the requisite knowledge of anatomy and of the use of instruments. Courage, which is so indispensable, is possessed by comparatively few ; the sight of blood, and the idea of inflicting pain, were so disagreeable to Haller, that, although he taught surgery with great success for seventeen years, he never, it seems, during all that time, performed a solitary operation upon the living subject. Courage, like poetry, has often been said to be a gift of nature, and nothing is, perhaps, more true ; but it is equally certain that a timid man may, by attention to his education, and by constant practice, become, in the end, a good operator. Habit does a vast deal for us in such cases, for it literally becomes a second nature. I know a surgeon who in his youth nearly fainted at the sight of blood as it flowed from a vein of the arm into the basin, which it devolved upon him to hold during the operation of venesection, and yet who, by a course of self-training and a complete knowledge of anatomy, has made himself a thorough master of the knife. Celsus, long ago, happily defined the qualities which constitute a good operator. He should pos-

ses, says the illustrious Roman, a firm and steady hand, a keen eye, and the most unflinching courage, which can disregard alike the sight of blood and the cries of the patient.

But the above are not the only qualities, important though they be, which an operator should possess. If he is not honest in his purposes, or scrupulously determined, in every case, to act only with an eye single to the benefit of his patient, and the glory of his profession, he is not worthy of the name which he bears, or fit for the discharge of the solemn duties which he assumes. In a word, such an operator is not to be trusted, for he will be certain, whenever opportunity offers, to employ the knife rather for the temporary eclat which may follow its use, than for the good of the individual whom he unnecessarily tortures. He will not hesitate to amputate a limb, although the patient should die the moment he is removed from the table, or to tie the carotid artery for a malignant disease of the eye, although he knows full well that such a procedure never has, in any instance, been of the slightest benefit. Such men, of whom there are, even yet, unfortunately, too many in our profession, deserve the name of knivesmen and knaves rather than of surgeons and honest men. No operation should ever be undertaken without due deliberation, and without a careful consideration of the various consequences involved in the result. Everything that is done should be done with reference exclusively to the patient; self should not have the slighest weight in the matter. The question, in every case, should be, is an operation necessary to save life, or to place the individual in a condition calculated to promote and insure his recovery? If this can be answered affirmatively, the operation should by all means be proceeded with; but if it be ascertained, clearly and satisfactorily, that it presents no such prospect, both humanity and common sense dictate the propriety of declining it. It is a sad and humiliating spectacle to see a surgeon cut off a limb, or remove a carcinomatous tumor, merely for the sake of having it said that he performed an operation. The conscientious and enlightened surgeon, unlike the heartless soldier, carefully respects life; he regards life as a great boon, and uses every possible endeavor to preserve and to prolong it. " I have been reared," said Napoleon, " on battle-fields, and such a man as I am makes no account of a million of men's lives."

No surgeon can be a skilful operator unless he has a thorough knowledge of anatomy. His acquaintance with the healthy structures and their relations with each other should be so clear and distinct that he should be able to see them as it were in a mirror, or with his eyes shut. He should carefully study their color and consistence, that, seeing and feeling them, he may readily distinguish them from each other, and not be obliged to ask his assistants whether this is an artery, that a nerve, or this a tendon, a muscle, or a ligament. Nor should he limit himself merely to the study of healthy and relative anatomy. He should also have an intimate and comprehensive knowledge of morbid anatomy, or of the changes which are impressed upon the organs and tissues by disease and accident, and also of the various growths, formations, and deposits. The information thus derived will be of the greatest aid in facilitating the different steps of the operation, and in enabling the surgeon to determine what to remove and what to spare.

No man can become an accomplished operator unless he practices constantly on the dead subject. Dexterity, grace, and elegance are to be acquired only by long and patient exercise. In all operations involving unusual anatomical complexity, a good plan is to make a thorough dissection of the parts immediately beforehand. Langenbeck, Lisfranc, Cooper, and Mott always adopted this method, and I have often profited by it in my own practice.

Preparation of the Patient.—No operation, unless it be of the most trivial nature, should ever be attempted without due preparation of the patient's system. The only exception to this rule is in case of emergency, where, in order to save life, we are obliged to act on the instant, without any precaution of this kind, and sometimes even without the necessary assistance. The character and amount of the preliminary treatment must, of course, vary in different cases and under different circumstances, and do not, therefore, admit of precise specification. It may be stated, in general terms, that, even if the patient be unusually plethoric, it will rarely be necessary to bleed him at the arm. In operations about the head, eye, and throat, this may be a wise precaution, but in most other situations this is uncalled for. In all instances it is well to take into the account the probable loss of blood that may take place during the operation. If this is likely to be considerable, all preliminary abstraction must be carefully refrained from, even in healthy, robust subjects; for there can be no doubt whatever that a copious, or even a considerable, loss of blood before, during, or immediately after an operation, has a marked tendency, in many cases, to retard recovery, and to dispose to the occurrence of erysipelas, pyemia,

tetanus, and other ill effects. Indeed, so thoroughly am I convinced of the truth of this remark that I feel as if it could not be urged too forcibly upon the mind of the practitioner. It was formerly thought that a certain amount of hemorrhage, under such circumstances, would not only do no harm, but that it would positively be beneficial, by rendering the system less liable to inflammation. Modern experience, however, has shown that such an opinion is utterly untenable.

In regard to the use of *laxatives* and purgatives, much judgment is required. While in many cases this class of remedies may be entirely dispensed with during the preliminary treatment, in others their exhibition is imperatively demanded. Their employment is especially indicated when the bowels are in an overloaded condition, or when there is some derangement of the secretion of the salivary glands, the liver, and mucous follicles of the alimentary canal, as denoted by the fetid state of the breath, the dryness of the mouth, the want of appetite, nausea, vomiting, or headache, or other other symptoms of malaise. The best articles for this purpose are blue mass and colocynth, or calomel and rhubarb, either alone, or in union with a small quantity of ipecacuanha or tartar emetic. The latter substances are especially valuable when there is much disorder of the secretions, with headache and loss of appetite. Occasionally nothing answers better than, or hardly as well as, a dose of castor oil, Epsom salt, or citrate of magnesium. Independently of their direct cathartic effect, purgatives are often extremely useful in clearing out the bowels, when, as, for example, in lithotomy and in anal fistule, it is desirable to prevent any action upon them for several days after the operation.

A proper regulation of the *diet* is generally of paramount importance. The extent to which this should be carried must, of course, depend upon the circumstances of each particular case ; but, as a rule, should not, on the one hand, be too rigid or protracted, and, on the other, not too abundant. Much of the success of an operation is often directly traceable to the attention that is bestowed upon this subject. In general it will be advisable to enjoin entire abstinence from meat and the coarser kinds of vegetables, coffee and strong tea, hot biscuit, pastry, condiments, and, in short, all articles of an indigestible and heating nature. The quantity of food taken in the twenty-four hours should also be less than ordinary, for nearly, if not quite, as much harm may result from an undue amount of mild and unstimulant food as from the moderate use of the more solid and substantial articles.

Instead of dieting and purging the patient, it may be necessary to feed and stimulate him before it is safe to use the knife. He may be exhausted, deficient in nerve-power, or pale and anemic, requiring a rich, concentrated animal, or mixed diet, milk, brandy, ale, or porter, and, perhaps, quinine and iron, especially the tincture of the chloride. Such a course is particularly indicated when there is a tendency to epidemic disease, lest the patient, from shock and loss of blood, should fall a ready prey to its effects. The employment of quinine is generally of immense benefit in all severe injuries, whether accidentally or designedly inflicted, in preventing erysipelas, phlebitis, angeioleucitis, septicemia, pyemia, and kindred affections, and in promoting recovery. This treatment is especially called for in persons living in, or coming from, malarial regions of country.

Finally, attention should be paid to the state of the body and *mind*. For some days, or even, perhaps, an entire week, the most perfect quietude should be observed, especially if the operation is at all likely to be of a serious character. If, for example, the object is to extract a foreign substance from the knee-joint, or to perform an operation for the radical cure of varicose enlargement of the veins of the leg, it is hardly possible to use too much caution in this respect. In such cases the patient should not only refrain from exercise, but remain recumbent much longer than usual, with the limb in an elevated, relaxed position. In ordinary cases a few days' confinement to the house will be quite sufficient.

Tranquillity of mind is a matter of great moment. All business cares should be laid aside, and no outward troubles of any kind be permitted to obtrude themselves during this probationary period. No unpleasant forebodings concerning the result of the operation should be indulged in ; or, if this be inevitable, the surgeon should exert himself to the utmost to assuage and mitigate them by proper explanations. In a word, it is his duty, in all cases, to encourage the timid and console the desponding by every means in his power. Many of our patients are from abroad, away from home and friends, and, therefore, peculiarly in need of sympathy.

Nothing depresses the powers of life more injuriously, or interferes more effectually with the reparative process than fear. It lowers the heart's action, disorders the secretions, and not unfrequently leads to the worst results. We now and then meet with a patient

who labors under an undefined apprehension that the operation to which he is about to submit will prove fatal. Every argument that the surgeon can employ fails to convince him; the impression is firmly fixed in his mind, and, if he does not die, his convalescence is sure to be tedious, and, for a long time, unsatisfactory. I never approach such a case without serious misgivings as to its final issue, and I question whether it would not be well, in such a condition, to refrain from the use of the knife altogether, at least for a time.

The influence of fear in depressing the vital powers is well illustrated in a case that occurred, in 1866, in the practice of Cazenave, of Bordeaux, in a man sixty years of age, who was about to undergo the bilateral operation of lithotomy. The surgeon was on the point of introducing the staff, when the patient, who had exhibited entire calmness and serenity during the preparations, was observed to become pale and faint, and in the course of ten minutes, in spite of all that was done, he expired. When this nervous syncope seized him, the instrument had not yet even touched him. A case of a similar nature occurred to Desault. An old man, suspected to be laboring under stone in the bladder, was about to be sounded by Civiale, but died of terror almost before the instrument had touched the meatus. Perrin refers to the case of a soldier, twenty-five years of age, affected with phimosis, who, reluctantly consenting to an operation, no sooner saw the surgeon's knife than he fell into a syncope and instantly expired.

The sudden supervention of grief, after a severe operation, often gravely complicates the case, by weakening, if not completely destroying, the efforts at restoration. The loss of a relative may, in such an event, unexpectedly cost a patient his life. The shock occasioned by the mental despondency violently depresses the system; the wound at once assumes an unhealthy aspect; the adhesive action is arrested; and gangrene, pyemia, or erysipelas finishes the work.

Anger operates in a similar manner. It disturbs the various functions of the body, especially those of the liver, and frequently destroys the process of repair, devitalizing the plasma that is effused between the opposed surfaces, and causing an amount of inflammation altogether incompatible with adhesive action.

Nostalgia is a powerful depressant; and in case of an operation, may, if not speedily relieved, exert a fatal effect. I am sure that I lost from this cause, in 1878, a child eleven years old, from whom I had removed sixteen days previously a small sequester from the lower part of the femur. The operation, performed under the influence of ether, was almost bloodless, and everything went on well during the first week, except that the child was terribly homesick, when gradually arachnitis showed itself, causing death at the end of nine days.

I have never put off an operation on account of the particular season of the year. When it is recollected that the gravest accidents, requiring amputation, occur every hour of the day, and every day of the year, such a precaution would seem to be entirely at variance with common sense, if not wholly useless. Nevertheless, I should certainly not advise the undertaking of any serious operation in extremely hot weather, if it were possible to postpone it without detriment to the patient. The same objection, however, does not lie against very cold weather, inasmuch as a good fire and a properly regulated temperature of the apartment may generally be obtained, without much trouble, even in midwinter and in the most rigorous climate.

No operation, even of the most trivial nature, unless imperatively demanded, should be performed during the prevalence of an *epidemic*. This remark is particularly applicable to erysipelas, which, under such circumstances, is almost sure to ingraft itself upon the wound, much to the detriment both of the part and system. During an epidemic of this kind in Kentucky in 1845, '46, and '47, the slightest abrasion of the skin, a leech-bite, or the application of a blister, was often followed by an obstinate, and sometimes even a fatal, attack of the disease; and the consequence was that I was compelled, for many months, to decline the use of the knife nearly altogether.

Age is, as a general rule, no barrier to an operation. Even infants at the breast have occasionally undergone the operation of lithotomy, and in certain congenital affections, as occlusion of the anus and urethra, the knife is obliged to be used almost immediately after birth. I am, however, as will be stated in its proper place, no advocate for very early interference in harelip; and I am clearly of opinion that it is best, as a general rule, to put off all severe operations in infants as long as possible, for it cannot be denied that they bear the shock and loss of blood, consequent upon such undertakings, much worse than persons of riper years and more developed constitutions. Very old people

often bear operations remarkably well, and recover from their effects with surprising facility. Pregnancy should always be considered as a bar to the use of the knife, except in those cases in which it is imperatively demanded to save life. Even the extraction of a tooth is occasionally followed by abortion or miscarriage, from the perturbating influence which it exerts upon the system.

The *habits* of the patient should not be disregarded in considering the question as to the propriety or impropriety of operative interference, for there can be no doubt that they frequently materially influence the result. Intemperance of every description, especially if long continued, always modifies the constitution, and renders it less able, as a general rule, to bear the shock and subsequent effects of the operation than in ordinary cases. In habitual drunkards mania à potu, erysipelas, and unhealthy suppuration are of frequent occurrence after the use of the knife. Huge feeders, or persons who are fond of the pleasures of the table, and who take little exercise in the open air, are scarcely less exempt from these affections. Inordinate sexual indulgence, the habitual loss of blood, and debility from previous suffering, often place the life of the patient in danger after a severe operation. Fat persons, and individuals of a doughy, inelastic constitution, do not bear the knife so well as the fleshy and more robust. The same is true, only in a still greater degree, of strumous people. Nervous, hysterical females are bad subjects for severe operations. Hospital patients, especially in the larger cities, do not, as a general rule, possess the same tolerance of the knife as private patients.

Should females be subjected to operations during the *menstrual* period, or immediately before its occurrence? Of the impropriety of such a course there can, as a general rule, be no doubt, and yet there may be exceptions even here. Certainly no sensible surgeon would extract a cataract at such a time, or remove a diseased mamma; or, in short, perform any serious operation, if it could possibly be postponed. But, on the other hand, daily observation teaches that women who are badly hurt during the menstrual period often make most excellent recoveries. I should, therefore, deem it perfectly proper to perform at least any of the minor operations at this time, and, in fact, almost any other where delay might prove prejudicial.

There are certain *diseases*, even some of which are not of a malignant character, in which surgical interference is wholly inadmissible, either for the time being, or altogether. I allude to those cases in which the malady demanding operation is complicated with other affections. Thus, in anal fistule, associated with tubercular phthisis, the knife should certainly not be used, unless the case is of an unusually distressing nature. The disease, in such a case, may be regarded as nature's issue, the drying up of which would almost be sure to be followed by an aggravation of the pulmonary symptoms. In stone of the bladder no one operates when there is serious organic disease of the kidneys, or even of the bladder itself. Amputation of a limb is never performed, except in cases of accident, when there is an aneurism of the heart; nor is the femoral artery ever tied for popliteal aneurism when a similar affection exists in the arch of the aorta. Persons laboring under diabetes do not bear operations well; their vital powers are always greatly depressed by the disease, and they are very liable to sink rapidly under injury, especially if attended with shock, or shock and loss of blood.

Persons affected with jaundice are bad subjects for operation. The blood, under such circumstances, is unusually dark, oozes freely from the cut surface, and is indisposed to coagulate. Besides, the adhesive process rarely advances kindly when the system is in this condition; the stomach and bowels are not easily regulated; and the slightest shock or hemorrhage may be followed by pyemia.

Indiscriminate operations cannot be too severely condemned, as they are injurious alike to the patient, the reputation of the surgeon, and the true interests of science. Like a prudent general, the surgeon should know when to retreat as well as when to advance. It is difficult to conceive of anything more laudable than a bold undertaking in a case which must prove fatal without speedy relief. At the same time, it would certainly indicate a degree of weakness, it not of absolute wickedness, to attempt an operation when there is not the slightest prospect of benefit.

There is a class of operations to which the French writers have applied the term *complaisance*, that is, operations of expediency, not of necessity. An individual, for example, has an infirmity, as a distorted foot, or a contracted finger, which is a source of annoyance rather than of suffering or even positive inconvenience; his pride is piqued, and as a consequence his mind is so incessantly disturbed by it as, perhaps, to be wholly disqualified

for business and social enjoyment. Such persons often importune the surgeon's aid, and it, therefore, becomes a nice question how he should govern himself. Shall he advise an operation, and run the risk of destroying his patient, or shall he refrain, and persuade him to bear his cross, for such it actually is? There can, I think, in general, be very little difficulty in arriving at a proper conclusion in such a state of things. For myself, I can see no difference between the physical suffering that is induced by a diseased bone and the mental distress that results from a deformed foot; so far as their effect upon the comfort and happiness of the individual is concerned they are precisely on the same level, and hence, if it be right and proper to amputate in the one case, why should it not be in the other? If a young man has a varicocele, even of moderate size, and it completely destroys his happiness and usefulness, not by its physical but by its mental effects, is it not our solemn duty to attempt relief by an operation, although the attempt should jeopard his life? I must confess, I should not hesitate as to the line of conduct to be pursued under the circumstances; at the same time, however, I should not omit to warn my patient of the risk he would be likely to run, and if, after a thorough explanation of the whole matter, he should still persist in his desire to be operated on, I should use every possible precaution, by a course of diet, rest, and other means, to put his system in the best possible condition for sustaining the shock of the approaching ordeal. Operations involving the same principle, although not the same risk, are of daily occurrence, and few surgeons hesitate to perform them: I allude more especially to the division of tendons in club-foot and strabismus, the extraction of the crystalline lens in cataract of one eye, when the other eye is sound, and other analogous affections.

Are double *synchronous* operations, or operations performed in immediate succession, justifiable? There can be no hesitation in answering this question affirmatively when the case is a comparatively simple one, as, for instance, when a man has several sebaceous tumors upon the scalp, or two or three small fatty tumors upon his back and shoulder. Here there could certainly be no impropriety, provided the system is in a sound condition, in extirpating all the morbid growths at one sitting. A similar course would be very proper if a hydrocele coexisted with a phimosis, a club-foot with a strabismus, a hemorrhoid with a polyp of the rectum. Even synchronous amputations are not unfrequently performed, and, occasionally, with the most happy results. A thigh has sometimes been cut off, and a skull trephined, at one sitting. Nevertheless, it is a good rule, one, indeed, which should seldom, if ever, be violated, not to perform two severe operations simultaneously or in rapid succession, if it be possible to avoid it, inasmuch as the shock and loss of blood thus entailed might be followed by fatal collapse or destructive inflammation. The rule is particularly applicable to chronic cases; in injuries, on the contrary, as gunshot wounds, railway accidents, and compound fractures, the surgeon may have no choice, as delay may then be altogether out of the question.

Assistants.—There are few operations which a surgeon can perform alone; in general, he is obliged to have assistants, and the number of these must necessarily vary in different cases and under different circumstances. Sometimes only one is required; at other times two, three, four, or even half a dozen will hardly suffice. The more simple an operation the less aid will commonly be necessary. In lithotomy an assistant holds the staff, two others support each a leg, one administers chloroform, another takes charge of the patient's hands, and a sixth presents the surgeon his instruments. In extracting a cataract, the operator usually requires only one assistant, to support the head and upper eyelid. Operations on children, especially when we are not permitted to employ anaesthetics, are often peculiarly embarrassing, and demand an unusual amount of aid for their successful execution.

The beauty, elegance, and rapidity, nay even the success of an operation, are often marred by the awkwardness of the assistants. To act well their part, they should be thoroughly acquainted with the different steps of the operation which is about to be performed, as well as with the nature and relations of the structures involved in it, so as to be able to anticipate every thought and wish of the principal. It is not necessary that they should be compelled, like so many Thespians, to rehearse the part which they are expected to play in the approaching task; but they should be thoroughly instructed in their business, and perfectly understand their duty, which should always be carefully explained and assigned beforehand. Nothing can be more awkward for a surgeon than to stop in the midst of an operation to ask for a knife, sponge, or ligature; once begun, everything should proceed with the utmost regularity, and without the slightest interruption from any cause. Good, well-trained assistants are, unfortunately, not always to be obtained; the older members of the profession are too much occupied to afford their

services, and the younger are too often ignorant of the duties required of them. These obstacles to success are usually much less in hospital than in private practice.

Duty of the Surgeon.—When the surgeon has perfect control of his time, as he almost always may have, except in cases of emergency, he generally selects a particular hour for performing the operation. The best period of the day, at least in this country, is from 11 to 3 o'clock, as he will then have the advantage of a good light, and also be in better trim for the discharge of his duty. An operation, especially an important one, should never, as a matter of choice, be performed late in the afternoon, or in cloudy weather; for, should hemorrhage arise, it might be very difficult to arrest it, on account of the want of good light, so indispensable on such occasions.

Artificial light may sometimes be used to great advantage in certain operations; and occasionally the aid of reflected light, as when it is thrown from the mirror of an ophthalmoscope, is of great service, especially in deep wounds, as those made in lithotomy, the ligation of the innominate and subclavian arteries, and the extirpation of tumors of the neck.

At the hour specified for the operation everything should be in its place; the assistants should attend with military punctuality; the table should be properly prepared; the anæsthetics, ammonia, and brandy, instruments, ligatures, sponges, water, and towels, should all be at the precise spot where they are required; in short, nothing should be wanting, but everything be at hand, and arranged in the most perfect order. I have heard of a surgeon, engaged in an amputation, making his flaps, and asking for his saw, which had been left in an adjoining room! A lithotomist performed the lateral section, and was about to introduce the forceps to extract the stone, when, lo and behold, the instrument had not been put on the tray! Such blunders might create a smile, if they did not sometimes involve serious consequences. It need hardly be added that all these preparations should be made in an adjoining room, away from the patient; it is enough for him to know that he is about to suffer, without seeing the instruments of his torture deliberately spread out, one after another, before his eyes. "The best general," said one of the greatest who ever lived, "is he who makes the fewest mistakes. Victory does not necessarily crown the best devised plan, but the want of one is almost certain to entail defeat."

Of the precise time, as to the day and hour, of the operation, the patient should usually be kept in ignorance, as the information, if made, could hardly fail to exert a perturbating, and, consequently, a prejudicial, influence upon the mind, and, through it, upon the general system. It is only in the milder cases that this intelligence should be communicated. There is, however, much difference in this respect in different individuals; for, while some would shrink from the disclosure, and be, perhaps, seriously affected by it, others will not only be indifferent to, but absolutely court it.

Position of the Patient and Surgeon.—The position of the patient, the surgeon, and the assistants must vary, of course, in different cases, and can be discussed here only in a general manner. When chloroform is to be given, absolute recumbency is required, to guard not only against delay, but also against the occurrence of serious mishaps. But, apart from this consideration, the horizontal posture should always be preferred whenever the operation is likely to be protracted, or attended with much shock and loss of blood. In other cases, again, as in lithotomy, the operation cannot be performed in any other posture than in the recumbent. In amputating the thigh and leg, as well, indeed, as the arm and forearm, the patient always lies down, not only on account of apprehended weakness, but because it is always easier, when he is thus placed, to hold the limb and control hemorrhage. In lacerating a cataract, the patient generally sits in a chair, with his head supported upon the breast of an assistant; in operating on harelip, the child usually sits upon an assistant's lap, the head being firmly held by another assistant, standing behind or by the side of the first. In lithotomy, the patient lies on his back, with the breech projecting over the edge of the table: two assistants support the legs, another holds the staff, a fourth takes charge of the sponges, and a fifth administers chloroform, while the surgeon sits on a low stool in front of the perineum, or, as I usually prefer, rests on one of his knees. Now that anæsthetics are so much in vogue, it is seldom that we are obliged to tie our patients, or to roll them up in sheets or aprons, as was the custom prior to the discovery of these agents.

The more important operations are generally most conveniently performed upon a firm, narrow breakfast table, well covered with blankets or comforts. Several pillows and folded sheets, and, if the case is likely to be a bloody one, a piece of soft oil-cloth, should be at hand, with a tray filled with sand or sawdust, to receive the discharges. Sometimes a lounge or sofa may conveniently be used; and, in many instances, the edge of the bed

answers very well. The patient should have as few clothes on as possible, for two reasons: first, that his dress may not be unnecessarily soiled, and, secondly, because it will afford him more freedom in breathing.

The surgeon and his aids should be careful, during the operation, that they do not, on the one hand, inoculate themselves with the discharges of the patient, and, on the other, that they do not communicate disease to him through their own persons, as might readily happen if they have recently been engaged in the dissection of patients dead of erysipelas, phlebitis, pyemia, or diffuse inflammation, especially of the peritoneum and of the pelvic veins of lying-in females. That there is frequently, if not generally, a virulent poison present in these affections, the influence of which may readily be disseminated by means of the hands and clothes, is fully established, and, therefore, every possible care should be taken to guard against all such contingencies. Accoucheurs often communicate disease and death in this manner from one parturient woman to another, and there are few practitioners extensively engaged in operative surgery, whether in private or public, who have not had similar experience among their own patients. A number of cases have been recorded in which surgeons in amputating limbs and excising tumors have contracted fatal diseases by the inoculation of their hands. In performing any delicate operation the hands should always be well washed and the finger nails thoroughly cleaned as a preliminary measure, in order that no dirt or perspiration may be deposited upon the wound, and thus become a source of irritation, interfering with the reparative process.

OPERATION.—Everything being thus prepared—the assistants being at their posts, the instruments arranged upon a tray in the order in which they are likely to be required, the parts divested of hair and dressings, and the patient fully under the influence of an anæsthetic—the operation is proceeded with, slowly, deliberately, and in the most orderly, quiet, and dignified manner. All display, as such, is studiously avoided; ever remembering, in the language of Desault, that the simplicity of an operation is the measure of its perfection. No talking or whispering should be permitted on the part of the assistants, and, as to laughter, nothing could be in worse taste, or more deserving of rebuke. Every important operation should be looked upon as a solemn undertaking, which may be followed in an instant by the death of a human being, whose life, on such an occasion, is often literally suspended by a thread, which the most trivial accident may serve to snap asunder.

The time occupied in performing an operation is a matter of some moment, but not so much, perhaps, as is commonly supposed. When a patient is unconscious, whether from cerebral oppression, or from the use of an anæsthetic agent, it is of very little consequence, other things being equal, whether the operation lasts five minutes or ten minutes, provided it is well executed, which it certainly cannot always be when we aim at great speed. Le Cat, it is said, lithotomized half a dozen patients in nearly twice as many minutes, and the result was that he lost nearly every one. Prior to the application of anæsthetics to the relief of suffering, rapidity was most commendable, inasmuch as it served to prevent shock and pain, although I am well convinced that it was often secured at the expense of much subsequent mischief, if not immediate detriment. The maxim of the schools has always been *cito, tuto et jucunde:* but, as it respects the first of these injunctions, it may be added, in the language of Cato, *sat cito si sat bene.*

Accidents during Operation.—The next topics to be considered are the accidents which are liable to take place during the operation, and the best methods of avoiding or meeting them. These are, first, hemorrhage, and, secondly, shock.

The amount of blood lost during an operation may be very small when measured by ounces, but very large in relation to its effects upon the system. Much will depend, in every case, upon the state of the constitution, and the temperament, habits, and health of the patient. A hemorrhage which may affect one individual very slightly, if, indeed, at all, may affect another most seriously and even fatally. A good deal, again, will depend upon mere idiosyncrasy, and upon the presence or absence of epidemic disease, which, as has already been intimated, generally impresses itself, to a greater or less extent, upon every individual in the community in which such disease prevails. Anything like a copious loss of blood is, as before stated, a great evil, and should, therefore, always if possible, be prevented. I cannot agree with those who think that the loss of twelve, sixteen, or twenty ounces will be likely to be beneficial, even when there is unusual vigor of constitution. If there be any undue vascular repletion, it can always be relieved, if the necessity arises, after the operation is over. In all cases, therefore, I deem it to be our duty to guard against hemorrhage as much as possible.

In amputations, the removal of necrosed or carious bone, the excision of bones and

joints, the extirpation of morbid growths, and all other surgical procedures upon the extremities, the field of operation may be rendered perfectly bloodless by the use of Esmarch's apparatus, which, as represented in figs. 204, 205, consists of an elastic bandage and an elastic flat band, the latter being preferable to the rubber tubing originally
Fig. 204.   Fig. 205.
Esmarch's Apparatus.

employed for constricting the limb above the last turn of the bandage. The bandage is applied by spiral turns, commencing at the toes or fingers, and when a sufficiency of the extremity has been covered, the band is wound rather firmly several times round the limb, and secured by the hook and chain. When the bandage is removed, the necessary incisions can be made without the loss of blood. Before the use of the compressing band, the constriction excited by the rubber cord was not infrequently followed by sloughing of the edges of the wound, but I have not met with examples of a similar nature since I have resorted to the former contrivance. If the band be too firmly applied it paralyzes the vasomotor nerves of the part, so that, after its removal, and the ligation of the principal arteries, there is free and prolonged bleeding from the smaller branches, thus leading to the necessity of employing a much larger number of ligatures than when the operation is performed according to the old method. Even when the constriction is merely sufficient to arrest the circulation in the limb, there is always pretty free capillary oozing, for the control of which Esmarch relies upon elevating the limb before the band is removed, as well as for half an hour after the wound has been dressed; Riedinger, to produce a similar effect, applies the faradic current to the wound. I myself have never had occasion to resort to these annoying and troublesome measures, as I have always found that the parenchymatous hemorrhage is readily controlled by retaining a cloth or sponge wrung out of water at a temperature of 110° to 115° Fahr. in the wound, and afterwards loosening the band very slowly. In operations for necrosis the bleeding is readily arrested by stuffing the wound with oiled lint before the band is removed. An ordinary bandage and tourniquet, such as I have used for the last forty years, in all my larger amputations, will, if properly applied, empty the vessels sufficiently for all practical purposes, and effectually protect the parts from this reaction, always so trying to the surgeon, if not fraught with danger to the patient. This method of preventing hemorrhage is contraindicated when a limb is the seat of gangrene or of collections of septic fluids, which might be pressed into the veins and lymphatic vessels and thus carried into the mass of circulating blood.

When the apparatus of Esmarch is not used, it is not necessary, or even proper, to tie every vessel as fast as it is divided. A well-trained assistant will generally obviate this necessity by compressing the bleeding orifice the moment the knife has swept beyond it, and by the proper exercise of this dexterity a large tumor may often be removed before a single ligature is applied. If the bleeding, however, be not controllable by this means, measures must be adopted to arrest it without delay by ligating the principal vessels from which it proceeds.

It is seldom, at the present day, that a patient sustains anything like serious shock from an operation, even if it be comparatively severe and protracted. The use of anæsthetics, if it do not always effectually prevent, generally restricts it within the limits of tolerance, and thus saves the surgeon a vast amount of trouble and anxiety. It is not, however, to be forgotten that the very means which are employed to prevent pain and shock may themselves induce severe, if not fatal, prostration. Hence, as will be seen by and by, too much caution cannot be used in their administration, the effects of the remedy being most carefully watched throughout, so that any symptom denotive of danger may instantly be recognized and counteracted. By keeping the patient perfectly recumbent

and providing for the free admission of air into the lungs, all mischief may, in general, be happily avoided. The syncope, caused by the loss of blood, is met by a depressed position of the head, by means of the fan, by dashing cold water upon the face and chest, by holding smelling-bottles near the nose, and, in severe and alarming cases, by sinapisms to the extremities, spine, and precordial region, aided, if necessary, by the use of stimulating injections, as brandy, turpentine, ammonia, or mustard.

Dressings and After-Treatment.—The operation being over, the next thing to be done is to adjust the dressings; these should always be as light as possible, and applied in such a manner as to insure the greatest chance for union by the first intention. The question has been much agitated, of late years, whether the dressings should be applied at once, the moment the knife has accomplished its object, or whether the parts should be permitted to remain free for several hours, to afford them an opportunity of contracting and becoming glazed with plastic matter. Much might be said in favor of both methods. The proper rule of practice, I think, is to steer a middle course, adopting neither plan exclusively. In large wounds, as those, for example, left in amputations of the thigh, leg, or arm, and in the extirpation of large tumors, the best plan always is to keep the parts open for three, four, or five hours, or until all oozing has ceased, and the raw surface has become incrusted with plastic matter, a light, porous towel, properly folded and frequently wrung out of cold water, being kept constantly applied to promote these occurrences. If, under such circumstances, approximation be effected immediately after the operation, the surgeon will often be compelled, a short time afterwards, even when he has taken the greatest possible care to secure the vessels, to remove his dressings, in order to arrest the flow of blood; a procedure which is generally not less painful and alarming to the patient than disagreeable and vexatious to the attendant. If, on the other hand, the wound is small, the best plan, I conceive, is to bring the edges together at once, as this saves both time and anxiety.

The dressings being applied, the patient is carried into his bed, previously prepared for his accommodation, and placed in such a position as will best promote his comfort and the reunion of the divided parts. Feathers and heavy quilts are to be carefully avoided; and, in general, it will be well, especially if there is a probability of there being much discharge, whether of blood, secretion, or excretion, to protect the bedding with a piece of thin, soft oil-cloth, spread beneath a folded, movable sheet. The affected parts are placed in an elevated and relaxed position, and maintained, throughout, in a cool, comfortable state. The diet must be light and unirritant, the drink cooling and palatable, and the temperature of the apartment from 65° to 72° Fahr. All unnecessary conversation should be avoided; and no persons, except the nurse and the immediate friends of the patient, should be permitted to enter the room during the first twenty-four hours after the operation, or, in cases of great danger and severity, not until a much longer time.

When an operation is performed in private, in the patient's own room, or in the apartment which he is afterwards to occupy, all extraneous material, as the table, sheets, towels, basins, and cloths, should be removed as speedily as possible after the work is over, and everything set in proper order, so that the patient, when he wakes from the effects of the anæsthetic, may find nothing, as he casts his eyes around him, to shock his feelings or offend his taste. It is impossible to bestow too much attention upon the æsthetics of the sick-room.

When the operation is at all severe, my invariable rule is to administer a full anodyne, generally a fourth or a third of a grain of morphia hypodermically immediately after it is over, or even sometimes an hour or two before it is commenced. The object is not only to allay pain, which is always a great desideratum, but to induce sleep and tranquillity of the system; in other words, to put the part, body and mind, all in a state of absolute repose for at least the first twenty-four hours after the use of the knife. By a full dose of morphia, I mean not less than one-third of a grain; a smaller quantity than this would only serve to fret and worry the patient instead of composing him. In cases of unusual severity, I do not hesitate to give half or even two-thirds of a grain, never forgetting that excessive suffering always establishes a certain amount of tolerance to the use of anodynes.

Too much attention cannot be bestowed upon the patient's diet. If the operation has been at all severe, or attended with unusual shock and loss of blood, he must be fed, not starved, in order to enable the system to reinstate itself as promptly as possible into its former condition, by the manufacture of blood and nervous fluid, both, perhaps, frightfully expended during the previous contest, and now in danger of being still further exhausted by the traumatic fever and the tumultuous action of the heart. The vessels must be

replenished; the brain and spinal cord supported. The most suitable articles for this purpose are milk and stale bread, with the free use of brandy, followed, in a day or two, by animal broths, beef essence, rich soups, and the lighter kinds of meats. Subacid fruits will also generally prove both grateful and nourishing. The drink should consist of iced water, either pure or acidulated, as may be most agreeable to the patient. A cup of tea or coffee is often exceedingly soothing and refreshing soon after a severe operation. Starvation after violent shock and loss of blood is frequently followed by the worst consequences, from the tendency in the system to run into erysipelas, pyemia, and hectic fever, independently of its incompatibility with the adhesive process.

The effects of diet upon mortality after injuries and operations are well illustrated by what occurred among the wounded soldiers that were received in the different hospitals of Paris in 1814. The table, drawn up by Malgaigne, included French, Prussians, Austrians, and Russians, the latter of whom had a liberal allowance of bread, vegetables, meat, wine, and even brandy, while the others were subjected to a strict dietetic regimen. The mortality among the French soldiers was 1 in 7, of the Prussian 1 in 9, of the Austrian 1 in 12, and of the Russian 1 in 27; an astonishing difference if we assume, as we are authorized, that it was due solely to a difference of treatment, and not to any peculiarity in the nature of the wounds, the surgical treatment, or the air of the hospitals in which the soldiers were accommodated.

But patients must not be fed indiscriminately after operations; when the individual is young and robust, perfectly temperate in his habits, and, above all, when he has not suffered severely from shock or loss of blood, his diet should be restricted and of the blandest character for a number of days, or, in fact, until the wound left by the knife is in great measure healed. Improper indulgence, under such circumstances, cannot fail to light up a fire which hardly anything afterwards may be able to extinguish.

If the patient has sustained severe shock or loss of blood, he should not only be well fed from the very beginning, but promptly subjected to the use of tincture of chloride of iron, in doses varying from twenty to thirty drops every three or four hours, as a preventive of erysipelas and pyemia, so liable to occur under such circumstances. Quinine may often be advantageously conjoined with the chalybeate, especially if the patient has been affected with malarial disease. Anodynes should also be freely exhibited.

Attention to the temperature of the patient's apartment is often a matter of great moment; in general, it will be best to regulate it by the thermometer, especially in operations on the respiratory organs, and after the extirpation of ovarian tumors. Everything like a direct draught must be carefully avoided; and in wet weather it will be well, especially if the moisture of the air be combined with cold, to employ artificial heat, while the doors and windows are sufficiently opened to secure proper ventilation.

The dressings should not be disturbed too soon, or oftener than is absolutely necessary to the comfort of the part and system. As a general rule, they require to be changed more frequently in warm than in cold weather, and in copious than in slight discharge. The proper practice is never to meddle with them so long as they answer the purpose for which they are applied. The sutures and adhesive strips should be removed with the utmost care; the substitute dressings should be prepared and ready for use before the old are taken off; the sponge should be employed with the greatest gentleness; in a word, all rude manipulation should be most studiously avoided. No bandage, however thoroughly washed, should be used twice, as it is liable, from the retention of matter, to become the carrier of infection, especially in large suppurating wounds and in compound fractures and dislocations. For the want of this precaution many a patient has perished from pyemia and erysipelas.

Some of the above precepts may seem trivial; but I am sure that they are of the greatest importance, and that the want of their observance is often followed by the worst consequences. It is a much easier matter to talk a patient to death, or to retard his recovery, after he has undergone a severe operation, or sustained a violent injury, than most people imagine. If symptomatic fever arise, or if the parts exhibit evidence of overaction, prompt recourse must be had to the usual antiphlogistic remedies, employed in a decided yet cautious manner, lest they produce harm instead of good.

The after-treatment should always, if possible, be superintended by the surgeon himself; his duty is not over with the operation; it ceases only with the cure or the death of his patient. "The practice," remarks an eminent authority, "of performing a serious operation, and leaving the after-treatment to others, has, in my knowledge, repeatedly proved disastrous. The medical treatment, a duty not less responsible than the operative, belongs

to the surgeon; and, indeed, to be employed merely as a handicraftsman, conveys an imputation at which the dignity of a scientific mind revolts."

An operation, if well performed, does not, in ordinary cases, require repetition. It is only, as a general rule, where it has been executed in a slovenly and imperfect manner that such a step will be likely to be necessary. Such an error is the more to be deprecated because the repetition of the operation may seriously, if not fatally, compromise the patient's life, after he has successfully surmounted the hazards of the first. If a tumor has been well excised, a limb properly amputated, an artery carefully ligated, there will seldom be any necessity for going over the same ground a second time. If, now and then, the reverse is the case, it only serves as an exception to an important rule. Repetition of an operation is most frequently required in malignant diseases, after lithotomy, and in amputations for the relief of gunshot, railway, and other severe accidents, where the injury often extends much farther up the limb than the eye can discover, and where, consequently, the most enlightened and skilful surgeon may be at fault.

Persons often submit with alacrity to the repetition of an operation when it promises to prolong life, or to afford even temporary relief from suffering; and recovery, under such circumstances, is sometimes very surprising. In a case of recurrent sarcoma of the mammary gland, described in a previous chapter, not less than twenty-three separate operations were performed before a cure was finally brought about. In a case of spindle-celled sarcoma of the neck, I excised the morbid growth five times, at varying intervals, with the effect of prolonging life for upwards of five years. Examples of lithotomy have occurred in which the patient was cut successfully four, five, six, and even seven times, as in the celebrated case of Grangeret.

Sources of Danger after Operations.—The great sources of danger, after a severe operation, are, first, excessive depression of the system from shock and loss of blood; secondly, traumatic fever; thirdly, undue inflammation of the parts; fourthly, secondary hemorrhage; fifthly, erysipelas; sixthly, pyemia; seventhly, tetanus; and, lastly, constitutional irritation.

α. The *prostration*, consequent upon an operation, is usually denoted by great pallor of the countenance, feebleness of the pulse and respiration, coldness of the extremities, yawning and sighing, partial blindness, dizziness, noises in the ears, restlessness, thirst, nausea, and even vomiting. To meet these symptoms, all that is generally necessary is to place the patient recumbent, to use heat, friction, and sinapisms, to allow free access of air, and to administer stimulants, as brandy, or brandy and ammonia, by the mouth, if the power of deglutition still remains, or, if not, by the rectum, in the form of enemata. A full anodyne will usually form a most valuable adjunct to these remedies, and should seldom, if ever, be omitted. Great care, however, must be observed in the management of these cases, lest violent reaction follow the depression, and hurry the patient on to a fatal termination. It is only in instances of extreme prostration that stimulants should be given boldly and freely, and without any regard to consequences in respect to the parts involved in the operation.

β. Great distress is often experienced after operations, especially if unusually severe or protracted, from nausea and vomiting, attended with more or less prostration, and not unfrequently very difficult of management. The exciting causes of this derangement are not always obvious, but in most of the cases that have been under my charge, the trouble was due to the effects of the anæsthetic, taken in excess, either from want of care in its administration, or want of proper coöperation of the patient. Ether, in particular, is liable to produce such effects, often extending over a period of many hours, or even several days. Occasionally the gastric disturbance depends upon the anodynes given to prevent or relieve pain, and promote sleep after the operation; and, in some cases again, it is evidently due to disorder of the secretions brought about by shock and loss of blood. A malarial state of the system, constipation of the bowels, a redundancy of acid or of bile in the stomach, organic disease of the liver or kidneys, and excessive thirst, may be regarded as so many predisposing causes. When the vomiting is very severe or protracted, it may lead to very serious, if not fatal, exhaustion. The treatment must be regulated by the nature of the exciting cause. In my own practice, I have generally found the best remedy to be a hypodermic injection of morphia, with the internal use of ice, and ice applied to the region of the stomach. Chloral and bromide of potassium are also valuable articles; and the use of bicarbonate of sodium in peppermint water is especially indicated when the distress depends upon the presence of acid in the stomach. When the patient is harassed with flatulence, iced champagne often affords prompt relief. Occasionally a mustard emetic answers an excellent purpose, especially in bilious vomiting. Passing a cloth

with a few drops of nitrite of amyl upon it rapidly before the nose, sometimes acts like a charm. In some cases, again, an irritating enema does more good in quieting the stomach than anything else. Now and then the most satisfactory remedy is a large dose of calomel. The best food is milk with lime-water and hot broths, taken in small quantity and frequently repeated.

γ. More or less *fever* must almost necessarily follow every severe operation, offering thus an additional source of suffering and danger to the patient, and of anxiety to the surgeon. To this disease the term traumatic is usually applied; the older writers called it bed or wound fever, and the late Sir James Y. Simpson gave a very excellent account of it under the name of surgical fever.

Fever generally sets in within the first six or eight hours after the operation, and is characterized by a flushed appearance of the face, a frequent, quick, and irritable state of the pulse, elevation of temperature, dryness of the skin, restlessness, and thirst, which is often excessive, especially after profuse losses of blood. In some cases there is extreme jactitation, with nausea, if not actual vomiting, and a tendency to delirium, or a confused and bewildered condition of the intellect. The breathing is generally somewhat hurried, and slight mucous râles are often present. The appetite is impaired or entirely wanting, the bowels are constipated, and the urine is scanty, high-colored, and often offensive, being surcharged with saline matters and occasionally even slightly albuminous. Now and then the disease is ushered in by distinct rigors. After the fever has continued for some time, a tendency to remit appears; the heat, thirst, and restlessness diminish, the pulse and temperature descend, the gastric distress vanishes, and the skin becomes covered with a gentle moisture, which often increases to profuse perspiration.

The duration of traumatic fever varies from a few hours to a number of days. In the milder cases it is generally very evanescent, while in the more severe it is often very protracted, and is then usually attended with regular vesperal, if not also matinal, exacerbations. Not unfrequently the disease disappears entirely for a few days, and then recurs, with more or less violence, the attack being provoked either by some dietetic or other indiscretion on the part of the patient, or by some change of the system, as the arrest of an important secretion, or the commencement of blood-poisoning.

The causes of surgical fever are sufficiently obvious. Every operation of the slightest severity, acts as a disturbing agent, depressing the vital powers, and deranging, as a direct and inevitable consequence, all the secretions. Familiar illustrations of these occurrences are daily met with even in very slight operations, as the lancing of boils, the extraction of teeth, and the abstraction of blood. The least shock, however induced, is sure to be followed by more or less general disorder, and it is hardly necessary to state that the amount of this disorder is always materially augmented when, in addition to the nervous lesion, there has been more or less copious hemorrhage. Nothing so rapidly or so powerfully irritates and frets the vascular and nervous systems as these two circumstances. The heart evinces its suffering first, by the feebleness and irregularity, and, after the occurrence of reaction, by the frequency and rapidity of its contractions. The nausea and vomiting, the excessive prostration, the yawning, and confusion of intellect, not to mention other symptoms, are unmistakable signs of the shock, or loss of power, sustained by the great nervous centres. The use of anæsthetics, doubtless, often contributes to the production of traumatic fever, by the disturbance which it occasions in the general system.

Now, if we take all these circumstances into view, and the fact that thousands of patients are subjected to operations without due preparation of the system, or, indeed, any preparation at all, as in cases of primary amputations, trephining, and the ligation of the larger arteries for the arrest of hemorrhage in gunshot and other wounds, it is certainly not necessary to invoke the agency of blood-poisoning, as is of late so frequently done, to account for the occurrence of traumatic fever. These causes are all sufficient to create the most violent disturbance; or, in other words, to set the whole system in a perfect state of ferment, subverting all its functions, and thus occasioning an amount of reaction capable of destroying life in a few hours, or, at all events, in a few days. While this perturbation is progressing, other and still more serious consequences may ensue, as erysipelas, pyemia, and effusions into the splanchnic cavities, the result of disordered secretion, and of the retention of hurtful matter, eventuating in a diseased state of the blood, and in a predisposition to local inflammation in parts more or less remote from the seat of the original injury. The constitutional derangement will, of course, be materially increased if, in addition to these disturbing agencies, there is an absorption or ingress of foul secretions into the system, constituting septicemia, or blood-poisoning.

The danger in traumatic fever is often very great, and it is, therefore, impossible to

watch the patient too attentively. The risk will be particularly imminent if the disease is very violent, or the system was much prostrated prior to the operation. The danger will then be twofold; first, from constitutional irritation and fatigue of the heart, leading to paralysis of its fibres; and, secondly, from internal congestion and local inflammation.

The proper remedies are cooling drinks, taken in moderation, or ice, if there be nausea, or gastric oppression; sponging the surface with cool or tepid water; mild laxatives; and the neutral mixture, or camphor water, with a minute quantity of antimony and morphia, to promote diaphoresis. If the symptoms are disposed to continue, more active measures may be required, especially purgatives, assisted, perhaps, by a few grains of calomel, particularly when there is marked disorder of the secretions. The lancet can seldom, if ever, be needed in any case. Leeching, cupping, and blistering may be necessary when there is congestion, or impending inflammation, of important internal organs. Local remedies must, of course, not be neglected. If the fever is obstinate, quinine will be indicated, combined, if there be profuse perspiration with a tendency to hectic, with iron and elixir of vitriol. The greatest possible attention is paid to cleanliness and ventilation.

This febrile commotion of the system is sometimes very deceptive, exhibiting an appearance of great violence, when in reality it is most slight, promptly yielding to the most simple remedies, or subsiding of its own accord. It resembles a sudden and violent storm, quite alarming, but altogether transient and harmless.

δ. The resulting *inflammation* will rarely exceed the adhesive limits, if proper care has been taken to prepare the patient for the operation, and the parts have not been too roughly handled during its performance. But prevention is not always possible, and hence the wound should be diligently watched, lest it be assailed, and even overwhelmed before the patient and his attendants are aware of the fact; for it should be remembered that the morbid action is not always characterized, under such circumstances, by the usual symptoms; there may even be an entire absence of pain and tension, perhaps even of discharge. Great vigilance, therefore, is often necessary to detect the earliest inroads of the disease, and to counteract its progress. Of course, all officious interference is avoided, and nature is carefully protected in the maintenance of her rights and privileges. The moment overaction is perceived, the dressings are either removed, or, at all events, slackened, suitable means being substituted. Of these the most important consist of leeches, water-dressings, and cataplasms, either simple or medicated, according to the exigencies of the case. If matter form, free vent is afforded, either by a change of position of the parts, or by puncture and incision. Constitutional treatment, of course, receives due attention.

ε. *Secondary hemorrhage* may come on within a few hours after the adjustment of the parts, or it may be postponed to a later period, even to a few days or weeks. It may be arterial or venous, slight or profuse, transient or persistent, as in the primary form of the accident. The most common causes are, imperfect ligation of the vessels, defective dressing, sloughing, and premature detachment of the ligatures. Whatever they may be, they should be carefully sought out, and at once counteracted by appropriate measures. The occurrence is always to be deprecated, because it has a tendency, not only to alarm the patient and his friends, but to impede and even to prevent the adhesive process, requiring, as it not unfrequently does, the reopening of the wound for its successful management. Fortunately, however, it is, in general, easily avoided, especially if proper attention be paid to the dressings and after-treatment.

ζ. *Erysipelas* is most apt to occur in persons of intemperate habits, or of a broken constitution, and usually makes its appearance within the first three days after the operation, generally at the site of the wound, or in the parts immediately around. Its presence is always denotive of disorder of the digestive apparatus, and hence one of the first things to be done is to administer medicines designed to clear out the bowels and to restore the secretions of the liver, the mucous follicles, and the salivary glands. For this purpose the best articles are calomel and compound extract of colocynth, or blue mass and rhubarb, followed, if necessary, by saline and antimonial preparations, with anodynes to allay pain and procure sleep. When evidence of debility exists, free use must be made of quinine, either alone, or, preferably, of quinine and tincture of chloride of iron, the latter especially being given in large and frequently repeated doses. The local treatment must consist, mainly, of dilute tincture of iodine, and solutions of acetate of lead, with punctures and incisions to relieve tension and afford vent to effused fluids.

η. *Pyemia* may set in almost at any time after an operation, but the most common period is from the third to the eighth day. It is usually ushered in by bold and well-marked symptoms, such as violent rigors alternating with flushes of heat, severe cepha-

lalgia, aching pains in different parts of the body, excessive restlessness, great thirst, a quick and frequent pulse, and inordinate dryness of the cutaneous surface. Delirium and extreme prostration soon ensue, and thus the case progresses from bad to worse, until, frequently in less than a week from the commencement of the attack, the patient expires in a state of utter exhaustion. Little is to be done for a system thus assailed. In nine cases out of ten the disease proves fatal. The proper remedies, at the start, especially if the patient is robust and plethoric, are moderate depletion, especially by leeches, the exhibition of the milder purgatives, as calomel and rhubarb, and mercury with a view to a rapid but gentle constitutional impression. When excessive prostration is threatened, brandy, wine, quinine, iron, and nourishing broths are indicated, and must be administered with a generous hand. Locally, besides leeching, iodine, blisters, and medicated fomentations will be advantageous: if matter form, early and free incisions are made.

g. Tetanus is fortunately a rare occurrence after operations in this country. It is most common in tropical regions. In Europe and North America it is met with chiefly in dissipated persons of a broken, dilapidated constitution. It would seem that in India the operation of lithotomy is occasionally followed by this disease, an effect which, so far as I know, is very seldom, if ever, witnessed in this country. Excessive loss of blood, severe shock, and exposure to currents of air, undoubtedly predispose to the occurrence, which usually shows itself within the first five or six days after the operation. The principal remedies, as indicated in the chapter on tetanus, are, anodynes, in full and sustained doses, atropia, chloral, quinine, iron, brandy, ammonia, and chloroform, with emollient applications to the wounded parts.

ι. Life may be assailed by *constitutional irritation* and profuse discharge, and that, too, long after all apparent danger is over. The patient gradually becomes hectic; his appetite and sleep fail; the bowels are irregular, at one time constipated and at another relaxed; and the parts, exhibiting an unhealthy aspect, refuse to heal. Such a state of things, which, in general, but too surely foreshadows an unfavorable result, is to be combated upon the same principles as hectic produced by ordinary causes.

x. Death sometimes takes place suddenly and unexpectedly after operations without any ascertainable cause, and where, at the time, everything seemed to be in a promising condition as to ultimate recovery. A more sad and distressing occurrence can hardly be imagined, and yet it is one which cannot always be avoided, no matter what precautions may be observed. Mere loss of blood, or shock, is not always sufficient to account for this unfortunate event, although in many instances it doubtless materially contributes to its production; for death not unfrequently happens where no such effects were witnessed. Nor can it be due to the introduction of air into the veins, as, for example, when operations are performed about the neck, inasmuch as, in this case, the patient either perishes instantaneously, or, at any rate, exhibits unmistakable evidence of the accident. Besides, this occurrence is not peculiar to operations upon the cervical region; it has been witnessed in operations upon all parts of the body, even in some of the more insignificant amputations and in the removal of small tumors. When there has been much loss of blood, or severe shock, the event is probably due, at least for the most part, to syncope, or actual paralysis of the heart, preventing this organ from transmitting a sufficiency of blood to the brain for the due performance of its functions; and such an effect is most likely to take place when the patient, through neglect, wilfulness, or mismanagement, sits up in bed, or stands on the floor, thus suddenly depressing the heart's action. In this way life is sometimes instantaneously destroyed in lying-in females, especially in those who have suffered seriously from hemorrhage; and similar results are occasionally witnessed after surgical operations and accidents. In another class of cases, death is probably caused by embolism, that is, by the formation of heart-clots, and of fibrinous concretions in the vessels, impeding the passage of blood, and so arresting, suddenly and unexpectedly, the functions of an important organ. It is well known that copious hemorrhage, or severe shock, invariably renders the blood more coagulable, and hence such a state of the system must be regarded as powerfully predisposing to the occurrence of embolism. It is not improbable that rupture of the heart from fatty degeneration is an occasional cause of sudden death after severe operations, especially when the use of the knife has been attended with inordinate nervous and muscular excitement.

It is sufficient for all practical purposes to know that such an event may occur after operations, without any formal attempt at its solution, which the present state of the science hardly enables us to do. Whatever the cause may be, no efforts should be spared to prevent it. For this purpose, the utmost care should be taken, after all serious operations, not to prop the patient up in bed, or to let him get upon his feet; nay, further, he should not, if he is very weak or exhausted, be permitted to move about in bed, or, in

short, to do anything tending to induce syncope, or promote the occurrence of embolism. The diet should be of a suitable kind, and such medicine should be given as shall have a tendency to impart tone and strength to the system. Free use, in particular, should be made of brandy and milk. If syncope occur, the head must immediately be placed low, and recourse be had to sinapisms and stimulating injections, to reassure the heart, although this will probably be in vain, especially if the cause of the failure of its action is the presence of a clot, either in its own cavities or in some vessel. As it is impossible to foretell, in any given case, when a patient may be exempt from sudden death, after severe shock, or great loss of blood, the precautions here enjoined should be rigidly observed until there is reason to believe that all danger from this cause is passed.

λ. Various *intercurrent diseases* may arise after an operation, and seriously compromise the patient's safety. The poison of an eruptive fever, as, for example, scarlatina may lie in the system in a state of latency before the operation, and after its performance break out in full force, perhaps within the first few days, the shock, hemorrhage, and disordered function contributing to its development, whereas, if no such disturbance had taken place its effects might never have manifested themselves. Malarial affections, supervening upon the use of the knife, often give rise to serious complications, greatly retarding recovery, if not inducing fatal results. A violent attack of dysentery, diarrhœa, gout, rheumatism, pleurisy or pneumonia, is always to be greatly dreaded after any serious surgical operation.

μ. The *mortality* of surgical operations is subject to numerous contingencies, some of which have an intimate relation with the patient himself, some with the nature of the injury, or accident necessitating the interference, and some with the surgeon, either directly or indirectly. It may be assumed, as a general rule, that all the capital operations, as they are termed, are attended with a certain degree of risk to life, while not a few of the minor or more insignificant ones have, from causes which it is not always easy to determine, a fatal issue. A man who undergoes a grave operation is like a soldier who engages in a fierce and bloody battle, with this difference, however, so far as danger is concerned, that, while the one is sure to be severely wounded, the other may escape without the slightest injury. The soldier who serves as a forlorn hope will stand a fair chance of being killed; and so will a patient who submits to the knife on account of some terrible accident or desperate disease. But such cases constitute the exception, not the rule; ordinarily, if the system is properly prepared, and the operation well performed, the surgeon looks with great confidence for a good recovery. If he could always select his cases, the general result would be very different. He would then not employ the knife against his judgment, as a dernier resort, with the certainty that there was hardly one chance out of a hundred for a favorable issue; he would let all the bad, desperate, or unpromising cases alone, to get well or perish, as a kind Providence might direct. But so long as a surgeon has any feelings of humanity he cannot do this; he must take the good, bad, and indifferent cases as they present themselves, and do the best he can with them. It is only when he is guilty of neglect, or of serious mismanagement, that he should be considered culpable. He does not expect to save all; he knows that many must necessarily perish, not so much as an effect of the operation as of the injury or disease for which the operation is performed, and, in attempting to estimate the probable result of his interference, he does not forget to take into the account the risk which his patient is obliged to incur from hemorrhage, erysipelas, pyemia, tetanus, and other intercurrent but often unavoidable affections. He is assured that there is no case, however apparently desperate, that may not recover, or one, however apparently insignificant, that may not perish.

The following tables will serve to show what has hitherto been the mortality after some of the so-called capital operations:—

Operations.	Cases.	Recoveries.	Deaths.	Per cent.
Lithotomy	11,584	10,246	1,338	11.11
Ligation of arteries	1,710	988	722	42.23
Herniotomy	622	326	296	47.57
Amputation of the thigh	2,011	1,150	861	42.80

But these results, so humiliating to surgery, refer chiefly to hospital practice, and can, therefore, hardly be considered as affording a fair average of the experience of the profession in general. The great majority of the most desperate cases, both of injury and disease, in all large towns and cities, find their way into public institutions, where they rapidly sink under the joint influence of vitiated air, erysipelas, pyemia, and want of proper attendance. It is a notorious fact that many more patients recover after bad injuries and severe operations in the country than in the city; and, to go no further, it may confidently be asserted that an experienced operator will lose fewer cases than one who is just commencing his career.

CHAPTER XVI.

PLASTIC SURGERY.

PLASTIC SURGERY is that branch of the subject which treats of the restoration of lost parts by the transplantation of healthy integument from some neighboring region. Originally restricted to the repair of the nose, it has, during the present century, busied itself, in different ways, with the emendation of various other organs, and has thus greatly enriched the domain of general surgery; having, in fact, created a new department of operative medicine, as fertile in its resources as it has already been brilliant in its results. The perfection which plastic surgery has attained within the last twenty-five years is truly wonderful, and affords a striking evidence of the ingenuity, talent, and enterprise of the medical profession in different parts of the world. It has literally been a field of conquests, upon which have been achieved some of the proudest triumphs of the human mind in modern times. Among the many names that are honorably associated with this department of surgery, on account of their persevering efforts to advance its interests, those of Carpue, Dieffenbach, Blandin, Zeis, Jobert, Serre, Liston, and Von Ammon of Europe, and Pancoast, J. M. Warren, Mütter, Buck, Post, Hamilton, Prince, and several others of this country, hold deservedly a high rank. Some of these surgeons have composed able treatises on plastic surgery, and have thus indelibly identified themselves with its history.

Various names have been devised to designate this branch of surgery. Thus, Blandin denominates it autoplasty, while Velpeau prefers the word anaplasty, such literally signifying reconstruction. By others the term plastic, from the Greek verb to mould, model, or adjust, is used, and this is, perhaps, less objectionable than any other; at all events, it possesses the advantage of being easily understood.

It is exceedingly probable that one branch of plastic surgery has been practised in India from time immemorial. In that country the barbarous custom has existed for ages of punishing certain classes of criminals by cutting off their noses, and there can be no doubt that sympathy for these poor wretches gradually induced persons to turn their attention to the means of affording them relief. Hence arose rhinoplasty, or the operation of making new noses, pursued chiefly by a low order of native priests, whose ignorance of the healing art was too profound to justify the idea that their efforts were often crowned with success. According to Galen, the ancient Egyptians were well acquainted with rhinoplasty, but self-interest and pride prevented them from communicating a knowledge of it to other nations. Whether the operation was ever performed in Greece and Rome history does not inform us, although it can hardly be supposed that, if it had been, it would have been silent upon the subject. In Europe attention was first prominently drawn to the restoration of lost parts by Gaspar Taliacozzio, Professor of Anatomy and Surgery in the University of Bologna. In a work on the subject, remarkable for its erudition, and the simplicity of its diction, published at Venice, in 1597, he has described with great minuteness the art of repairing mutilated noses, lips, and ears, illustrated by numerous engravings. It bears the title of "De Curtorum Chirurgia per insitionem," and is curious as furnishing a record of the observation and experience of a truly great surgeon soon after the revival of learning. His practice must have been very great as a rhinoplastic surgeon, for it is distinctly stated that patients visited him from all parts of Europe. The pupils of Taliacozzio, settling in different parts of the continent, took great pains to disseminate a knowledge of the operation among the profession, although it does not seem to have been often applied in practice, doubtless from fear of failure. The operation, moreover, was doomed to encounter many obstacles from ridicule, which always exerts a powerful influence upon the weak and prejudiced in every country, and not unfrequently has the effect of throwing a new and useful invention completely into the shade.

The method of Taliacozzio consists in borrowing the required material from the arm; the operation is very tedious and complex, and has been almost entirely superseded by the Indian method, in which the flap is taken from the forehead. These two processes

will be described in their proper place. Meanwhile, it may be observed that the Oriental operation was first successfully performed in Europe in 1814, by Carpue, of London, who, in 1816, published an account of this and of another case, equally fortunate. To Dieffenbach, however, more than to any one else, is due the merit of having first generalized the operation, by pointing out the sphere of its application.

The nomenclature of these plastic operations has assumed quite an imposing character, from the numerous structures to which they are applicable. It is formed by adding the word "plasty" to the anatomical name of the part concerned, as rhinoplasty, genioplasty, and urethroplasty. Before I proceed to speak of these operations separately, it will be necessary to offer some remarks of a general nature respecting the causes which necessitate them, the preparation of the system, the proper mode of conducting them, and the character of the after-treatment.

The causes necessitating these operations are various kinds of accidents and diseases. Thus, in India, as already stated, rhinoplasty is generally required on account of wilful mutilation of the nose as a punishment for crime; in Germany, on the contrary, it is often called for on account of injury sustained by the small sword in duelling. The vicious cicatrices left by burns and scalds frequently lead to the necessity of their performance; in fact, a large field for plastic surgery has been opened in this class of lesions, in which good service was rendered by the late Dr. Mütter, since attention was first directed to it. Of the various diseases which may create a necessity for this kind of interference, carcinoma, struma, and syphilis occupy the first rank, these affections not unfrequently destroying the greater portion of the nose and lip, and thus causing the most disgusting deformity. Genioplasty is generally required on account of ulceration of the cheek from the effects of mercury; and urethroplasty, in consequence of urinary fistule, the result generally of stricture and abscess.

Whatever may be the causes leading to the necessity of these operations, none should ever be undertaken without thorough preparation of the system, extending through a number of days, if not several weeks. Upon this subject it is impossible to insist too strongly. I have seen enough of these cases to satisfy me that too little attention is paid to preliminary treatment, and that most of the failures which attend the procedure are due to the neglect of this precaution, for which there is the less excuse, seeing that there is never any need of immediate interference. There is no necessity, unless the patient is very plethoric, for the use of the lancet; light diet, rest, and an occasional purgative will generally suffice to bring down the system to a proper point of tolerance for the approaching ordeal. If the patient is from abroad, he must not be molested until he has recovered from his fatigue, and become accustomed, in some degree, to his apartment and to those who are to attend to his wants. His room should be spacious, cheerful, and well ventilated. If the weather be cold, the temperature should be regulated by the thermometer, uniformity in this respect being of paramount importance to the success of the enterprise. No operation of this kind should be undertaken in the heat of summer, or during the existence of any bodily ailment.

It is hardly necessary to state that no plastic operation should ever be attempted so long as the disease necessitating it is not completely eradicated from the part and system. It would be the height of folly, for example, to undertake the restoration of a nose lost in consequence of syphilis if there were any traces of this affection, in any portion of the body, however remote, or however distinctly connected with the disfigured organ; for there could be no possible guarantee here that the disease might not attack the new nose or the adjoining parts of the old, and so frustrate the design of the surgeon. Besides, even supposing that such an untoward occurrence did not take place, still, it would be improper to operate, because the subjects of this disease are not only very prone to erysipelas, but wounds in them generally unite with more difficulty than in healthy persons. The same remarks apply to struma, although I have great doubts whether this disease, by itself, ever destroyed any nose, ear, or lip. The mischief that is so often ascribed to it is nearly always done by syphilis, or by a combination of these affections from the transmission of the two poisons from the parent to the offspring. It is different with carcinoma. Here the plastic operation may, generally, be performed immediately after the excision of the offending disease.

The manner of executing the operation relates to the position of the patient, the surgeon, and the assistants; the administration of the anæsthetic; the mode of selecting, making, and fastening the flaps; and several other circumstances which it is not necessary to specify.

If the operation be very simple, and likely to be soon over, the patient may sit up;

otherwise he should lie down, his head and shoulders being properly supported by pillows. The surgeon and the assistants should dispose themselves in such a manner as may seem most useful for the prompt and successful execution of the operation. An anæsthetic is proper in almost every case, since the operation is frequently not only very tedious, but it is always desirable that the patient should be as passive as possible while it is in progress.

There are, as has already been stated, two points from which the integument may be transplanted for filling up the chasm in the mutilated organ; either from the immediate vicinity of the part or from a distance. Thus, in making a new nose, or mending an old one, the flap may be taken from the forehead, according to the Indian method; or, if the gap be very small, even from the cheek, at a still shorter distance from the nose. Or the surgeon, adopting the plan of Taliacozzio, now known as the Italian operation, may borrow the necessary material from the arm, although this method, owing to its tedious and complicated character, has become almost obsolete. In some cases the flap is obtained by a kind of migratory process, being successively transferred from one region to another until it reaches its final destination. Roux in this manner attempted to close an opening in the cheek, by inserting a piece of the lower lip into the upper, and, after a time, when the parts had contracted thorough adhesions and become accustomed to each other, transferring it to the place which it was intended to occupy permanently. Such a procedure would seem, at first sight, to be puerile, but upon reflection it will readily be seen that cases might arise where it would not only be justifiable but very proper.

However obtained, it is important that the integument should, if possible, be perfectly sound; free, not only from disease, but from scars. The necessity of attention to this rule is too obvious to require comment. A cicatrice, having only a low vitality, is extremely apt to slough when transplanted. A sickly graft cannot take root on a sound bough, nor will a diseased bough permit the growth of a sound graft. To unite and maintain their future relations both must be healthy. Another point of consequence is that the flap should be as destitute as possible of hair; for, although it might be divested of this after it has grown fast in its new position, it is always best not to incur any risk of unseemliness from this source.

The size of the flap must, as a general rule, be at least one-third larger than the opening which it is intended to cover, to allow for the necessary shrinkage. If the integument be very thick, the contraction will be less than under opposite circumstances, but even here it is well for the surgeon to be on his guard, lest, when the cure is completed, the result should disappoint him. The shrinkage is always gradual, and generally continues for many months after the operation, the part gaining in thickness and density what it loses in circumference.

The shape of the flap must accurately correspond with that of the gap which it is destined to close. Hence the best plan is always to define its outline before the operation by means of a pattern, placed upon the surface whence the integument is to be taken, and marked off with ink, nitrate of silver, or, what is better than either, tincture of iodine.

The composition of the flap is a matter of paramount importance. It should consist merely of skin and connective tissue, with a small quantity of adipose substance, muscular fibre, nerves and veins being carefully excluded. The presence of a thin layer of fat is always conducive to the preservation of the flap, as it tends to protect the subcutaneous vessels, and facilitate adhesion. A large pedicle must always be left, otherwise the part may die from inadequate supply of blood and nervous fluid. No large artery should be embraced in it, as this would convey more blood into it than would be required for its nutrition, or than the veins could return.

These preliminaries being disposed of, the surgeon with a sharp scalpel pares the edges of the part to be repaired, vivifying them with great accuracy, and removing all redundant and callous matter; or he may first dissect up the flap, and do the paring afterwards, as fancy or convenience may dictate. In executing this step of the operation, great care must be taken not to press or pinch, either with the finger or forceps, any portion of the flap or old skin, but to leave everything in as natural condition as possible, since nothing will so readily promote reunion. The edges may be bevelled off or cut straight, according to circumstances, as will be more particularly described hereafter. The dissection is frequently attended with smart hemorrhage, but the rule is never to apply any ligature to the flap, lest it should interfere with the adhesive process, although any vessel of the wound that may spirt should at once be secured, and the wound itself promptly closed by suture. More or less gaping will of course remain, but

it is astonishing how small a cicatrice is usually left even in the most extensive lesions of this description.

All bleeding having ceased, the flap is gently sponged, and accurately stitched to the edges of the chasm which it is designed to close. The most eligible suture will be found to be the interrupted, with an interval of two to three lines between the threads, the ends being tied with a slip-knot over a narrow roll of adhesive plaster. The advantage of this procedure is that the suture may be loosened at any time if it be found to be too tight. Much harm is often done by placing the stitches too closely, the effect being to cut off the circulation. The twisted suture is objectionable for the reason, first, that the needles are, in many places, difficult of introduction, and secondly, that they are liable to cause too great a degree of tension. The grooved suture, so happily used in plastic surgery by the late Professor Pancoast, will be described in connection with rhinoplasty, to which it is more particularly applicable.

The dressing is completed by covering the edges of the newly related parts with lint, spread with simple cerate, or wet with olive oil, in order to prevent them from becoming dry and shrivelled, an effect very liable to happen when this precaution is not duly attended to. The surface of the flap may be protected with dry lint, or, what is generally preferable, be exposed to the air. If it is very large, it will be necessary to confine it lightly in its place with adhesive plaster and a bandage, but anything like firm pressure must be carefully avoided. The wound from which the flap has been borrowed is dressed with cold water, and a similar application may be made to the amended organ if appearances indicate that there is a likelihood of overaction. The operation being completed, the part is kept at rest in a relaxed and elevated position; a light, cooling diet is enjoined; and the air of the apartment is carefully regulated by the thermometer, an equable temperature being of the greatest consequence to the welfare both of the part and system. A full anodyne is given the moment the patient is put to bed; but, if things go on well, the bowels must not be disturbed under forty-eight hours, when they may be opened by a cooling laxative.

The sutures may be removed, on an average, from the fifth to the seventh day; but so long as they are doing well they should not be disturbed, and there are few cases in which it is proper to take all away at once. Great attention to cleanliness must be observed, and the best mode of effecting this is to irrigate the parts occasionally with the syringe.

If undue swelling and discoloration arise, the patient must be promptly bled and purged, and such local means employed as are best calculated to meet the emergency of the case. Leeches may be applied to the neighborhood of the flap, but not to the flap itself, for fear of exciting erysipelas. Occasionally a considerable flow of blood may be obtained by slightly lifting the flap at one or more points, the bleeding being encouraged with a sponge and warm water.

The great danger after an operation of this kind is erysipelas, which may be so considerable as to destroy not only the flap but also the patient. Such an occurrence should be promptly met by the topical use of the dilute tincture of iodine, and by appropriate internal remedies, especially quinine and iron, aided, if there is any tendency to a typhoid state of the system, by stimulating drinks and a generous diet. Now and then a patient is lost by pyemia, but such an event is fortunately very uncommon. Gangrene of the flap, either from inadequate nutrition, overaction, or undue constriction, occasionally occurs, and mars the success of the operation.

For a time the flap remains pale and cold, but these effects soon pass off, and are succeeded by a bluish appearance and an increase of temperature. The circulation is evidently temporarily embarrassed, the arteries conveying blood faster to the part than the veins can remove it. Hence a certain degree of stagnation ensues, followed by a bluish, threatening condition of the part, which, however, soon disappears spontaneously. Natural sensation does not return for a long time; it begins first along the edges of the flap, and thence gradually extends over the rest of its surface. For the first few months the transplanted skin may appear unnaturally large and unseemly; gradually, however, it becomes smaller, and eventually it may shrink so much as to answer but imperfectly the objects of the operation.

One of the latest improvements in plastic surgery is skin-grafting, an operation introduced, as stated in a previous chapter, in 1869, by Reverdin, and consisting in the transplantation of a bit of skin, hardly the size of a mustard seed, among the torpid granulations of an old ulcer or any raw surface indisposed to heal. Union soon occurs, and in a short time the little bud becomes the centre of a new growth,

standing, island-like, in the middle of the granulations, and serving as a point of departure for the formation of new skin. What is remarkable is the well-attested fact that epithelial scales, scraped from the cutis, and applied to the granulations of an ulcer, speedily contract adhesions, and answer nearly, if indeed not quite, as well for the purpose designed as the more perfect skin.

CHAPTER XVII.

SUBCUTANEOUS SURGERY.

SUBCUTANEOUS SURGERY is one of the creations of modern times, due chiefly to the genius and intrepidity of one man, Dr. Louis Stroymeyer, of Hanover, who was the first to practice, upon a rational and philosophical plan, a subcutaneous operation, the undertaking consisting in the division of the tendo Achillis for the cure of clubfoot. The operation was performed in February, 1831, and eventuated in the complete restoration of the use of the limb. Prior to that period several attempts had been made, by different surgeons, as Lorenz, Thilenius, Michaelis, Sartorius, and Delpech, to relieve this complaint, but they had all signally failed, simply because they had not been based upon correct scientific principles.

Since the discovery of Stromeyer, the domain of subcutaneous surgery has been greatly enlarged, by the application of its principles to other parts of the body, for the relief of which it has already performed the most valuable services. Dieffenbach, in 1839, gave it a new impulse by devising the operation for strabismus, which, although not practised by him subcutaneously, did much to inspire new confidence in the procedure, and to awaken a new interest in its application. Soon afterwards, however, the section of the muscles of the eye was performed without external wound, by Guérin, but the operation, if not obsolete, has never met with much favor by the profession. The French surgeon has extended the subcutaneous practice to the treatment of lateral curvature of the spine, by the division of the muscles of the back; and, at a more recent period still, it has been applied to the relief of numerous other affections, which would hardly admit of cure in any other manner. Among the more important procedures that have grown out of this branch of surgery are the removal of cartilaginous bodies from the joints, the radical cure of hernia, the reduction of chronic dislocations, the evacuation of abscesses, the cure of ankylosis, and the obliteration of serous cavities. Too short a time has elapsed since the discovery of subcutaneous surgery to enable us to form a just estimate of its limits, or the extent to which it may with propriety be carried into practice; but it is not difficult to perceive that in a field affording such unbounded opportunities for the exhibition of display and selfishness, much abuse must creep in, which time alone will be able to rectify.

The practice of subcutaneous surgery is founded upon the great law that all wounds and injuries occurring without an opening in the integument unite with very little, or, according to some, with no inflammation, and with no suppuration, differing thus essentially from similar lesions accompanied with a solution of continuity of the skin, which are always followed by considerable inflammation, and also very frequently, if not generally, by a discharge of pus. This law, which is now universally recognized by surgeons, was clearly enunciated by John Hunter, in his writings, near the close of the last century, but did not attract the serious attention of his countrymen until within a very recent period; not, indeed, until the facts of the subcutaneous section had been placed upon a firm and immutable basis by the practitioners of the continent of Europe. The idea of the illustrious Englishman lay in his writings, like a pebble upon the sea-shore, often seen but never observed, until accident directed attention to it years after the establishment, by others, of the great principles which he had so clearly enunciated. One reason, perhaps the chief one, of this was that he himself had never performed a subcutaneous operation: if he had, there is certainly no evidence of the fact in any of his writings. The only passage in his works which has any relevancy to the present subject is the following:—" The injuries done to sound parts, I shall divide into two sorts, according to the effects of the accident. The first kind consists of those in which the injured parts do not communicate externally, as concussions of the whole body or of particular parts, strains,

bruises, and simple fractures, either of bone or tendon, which form a large division. The second consists of those which have an external communication, comprehending wounds of all kinds, and compound fractures. Bruises which have destroyed the life of the part may be considered as a third division, partaking, at the beginning, of the nature of the first, but finally terminating like the second. The injuries of the first division, in which the parts do not communicate externally, seldom inflame, while those of the second commonly both inflame and suppurate." It is evident, from the tenor of this passage, that Hunter had carefully studied the influence of the air upon the healing of wounds, but it is not very clear, from aught that appears in it, that he had any conception whatever of the nature of subcutaneous surgery, properly so called.

Several of what are now dignified as subcutaneous operations have been performed for a long time. The mode of evacuating chronic abscesses by a valvular incision, first practised by John Abernethy, early in the present century, legitimately belongs to this division of surgery, its object, as clearly enunciated by the originator, being the exclusion of the air, on the ground that the contact of this fluid with the pus in the interior of the sac is the cause of the excessive local and constitutional disturbances which so often follow the old mode of opening these collections. Of the value of this procedure there can be no doubt, although the class of cases which it is intended to relieve is, from their very nature, unfortunately too often fatal. The operation of dividing the stricture in strangulated hernia, external to the sac, originated with J. L. Petit a century and a half ago, but has only of late years received the attention it merits. Some of the English practitioners, commencing with Ashton Key, have recently bestowed much attention upon the subject, and have adduced a body of testimony in its favor highly flattering to this mode of treatment. The object of the operation, the advantages and disadvantages of which will be considered in their appropriate place, is, by relieving the bowel subcutaneously, to guard against the occurrence of the severe inflammation which so frequently attends the ordinary procedure, even in the hands of the best practitioners. The injection of hydrocele with irritating fluids, as suggested by Sir James Earle, early in the present century, is another instance of a subcutaneous operation, which has long been familiar to the profession, and been practised by every enlightened surgeon in Europe and America. Some recent writers have gone so far as to class the use of the seton in the treatment of ununited fracture among the expedients of subcutaneous surgery: such an application is certainly carrying this department altogether beyond its legitimate limits, and is, therefore, calculated to do the subject much harm by giving to it a wrong direction. The wound made by a seton is, to all intents and purposes, an open wound, followed not only by high inflammation, but by profuse suppuration; occurrences which it is the peculiar province of subcutaneous surgery to guard against. A better example of a subcutaneous operation, performed for the relief of ununited fractures, is the division by means of a long, slender knife, of the soft tissues which form around the ends of the broken bone, the raw surfaces being afterwards approximated and maintained by appropriate apparatus.

On the whole, regarding subcutaneous surgery in its legitimate application, it appears to me that the cases to which it is adapted are susceptible of being arranged under the following heads: 1. Cases involving the division of tendons, muscles, bones, and aponeuroses for the relief of various distortions, as clubfoot, clubhand, spinal curvature, knockknee, and strabismus; the reduction of dislocations, especially those of the foot; and the cure of ankylosis of the joints, depending upon contraction of the soft parts. 2. Operations for the radical cure of hernia, whether by puncture or injection: and division of the stricture in strangulated hernia external to the sac. 3. The evacuation of chronic abscesses and of purulent, serous, and sanguineous collections of the chest and other cavities, by a valve-like opening of the skin. 4. The withdrawl of cartilaginous concretions from the joints, as originally suggested by Goyrand and Syme. 5. Operations for obliterating serous cavities, when, in consequence of inflammation, they become occupied by serous fluid; as the vaginal tunic of the testicle, certain synovial burses, especially those about the hand and wrist, and various adventitious cysts, particularly those which are so liable to form in the neck in connection with the thyroid gland. 6. The comminution, by the knife, of diseased lymphatic glands, the incision of inflamed periosteum, and the division of morbid adhesions, as those existing in chronic luxations, in depressions of the nose, and similar affections. 7. Forced extension of ankylosed joints, rendered so by the formation of fibro-ligamentous bands. 8. The subcutaneous obliteration of vascular tumors, by ligature or injection. 9. The operation for the radical cure of varicocele. 10. The relief of deformities of the hip-joint by the division of the thigh bone, as originally practised by Barton, and more recently by Sayre, Adams, Volkmann, and other surgeons.

The mode of operating for subcutaneous purposes must vary of course according to the particular indication which it is designed to fulfil. Whatever, however, the object may be, the rule is to make as small an external wound as possible, consisting, in fact, rather of a puncture than an incision, for it is ever to be borne in mind that one of the cardinal aims of every procedure of the kind is the exclusion of the air. The knife with which the operation is performed must, therefore, always be very narrow, sharp-pointed, and rather short, a length of edge from half an inch to an inch being a good average. The annexed sketch, fig. 206, represents the knife which I have long been in the habit of using in all my subcutaneous operations. Such an instrument is generally much more manageable than a longer one, while one of greater width would make too large an opening. If the object be to evacuate an abscess, a medium-sized trocar

Fig. 206.

Tenotome.

may be used, the skin having previously been divided with a bistoury. The instrument is then passed for a variable distance—usually from an inch to an inch and a half—through the subcutaneous connective tissue, when its point is plunged into the pyogenic pouch, its entrance being denoted by the want of resistance and the escape, perhaps, of a few drops of thin pus. In extracting cartilaginous concretions from the joints, a delicate knife is carried along under the integument through the capsular ligament and synovial membrane, which are then divided to a sufficient extent to admit of the displacement of the morbid growth, previously fixed by the thumb and fingers, into the connective tissue external to the articulation, from which, after the wound is healed, it is removed by a second operation. The operation for the radical cure of hernia, requiring instruments of particular construction and use, will be described in its proper place, and so in regard to several other procedures which cannot be here noticed.

All operations of this kind should be performed with great gentleness and care; for whenever this is done, there will be no risk either of severe inflammation, or of the division of any important vessels, nerves, or other structures not concerned in the particular affection for the relief of which the procedure is undertaken. I do not agree with those who maintain that tendons and other textures may be cut without the operation being followed by inflammation; on the contrary, I am convinced that a certain degree of incited action is present in every instance, and, if this view be correct, it proves how important it is that it should be kept within proper limits. This subject, however, will again be adverted to in speaking of tenotomy. In general, the little puncture made in the operation unites in a few hours, while the gap which intervenes between the retracted ends of the divided structure is gradually filled up by plastic matter, which is eventually converted into analogous tissue.

Most subcutaneous operations are nearly bloodless, a circumstance which constitutes one of their leading peculiarities. While open wounds always bleed, to a greater or less extent, those made beneath the skin by a narrow, sharp-pointed knife, used with proper care, are almost free from hemorrhage. In dividing the tendo Achillis for clubfoot, frequently not more than a few drops of blood are lost. As to shock, or serious depression of the nervous system, consequent upon such an operation, such an occurrence is never witnessed. The procedure, however, is not always free from pain, especially during the efforts which are sometimes required to straighten the affected part after the division of the faulty structures; and hence it is often useful to administer an anæsthetic, the more so, because this not only prevents suffering, but, by rendering the patient passive, gives the surgeon more complete control over his own movements.

Active preparatory treatment is rarely required in these operations. I have frequently performed the most extensive tenotomy at the College Clinic, as well as in private practice, upon children whom I had seen for the first time only an hour before, and yet in no instance, so far as I have been able to learn, have any bad effects followed. The operations, however, for the radical cure of hernia, for breaking up adhesions in ankylosis, for the removal of cartilaginous bodies from the joints, and for the relief of some other affections, always demand more or less attention of this kind.

The after-treatment, for the first few days, is generally very simple. As soon as the operation is over, the little wound is covered with adhesive strips, to exclude the air, and the part, surrounded by a bandage, is maintained in a perfectly easy, quiet position. If active inflammation arise, which, however, is seldom the case, the usual antiphlogistics

must be employed. After nearly all such operations suppuration must be prevented at all hazard.

When the operation is practised for the relief of some deformity, as clubfoot or spinal curvature, the cutting constitutes only a trivial part of the procedure. The great care and trouble of the case come afterwards, in the fitting and wearing of the necessary apparatus. It is usually recommended that no apparatus should be used until after the lapse of several days, or until the primary effects of the operation have passed off. I have, however, in many cases, so far deviated from this rule as to confine the affected limb at once, and usually without any disadvantage. Indeed, I am strongly inclined to believe that this ought to be the rule, and delay the exception. As this subject, however, will be considered in connection with the various operations to which it relates, any further remarks upon it here would be out of place.

CHAPTER XVIII.

AMPUTATIONS IN GENERAL.

SECT. I.—INTRODUCTORY CONSIDERATIONS.

THE word amputation was formerly, and is occasionally even yet, employed to signify the removal of various kinds of tumors; thus, many of the older writers speak of amputation of the breast, amputation of the jaw, and amputation of the scrotum. At the present day, however, the term excision is generally used as more appropriate in connection with these procedures, while that of amputation is applied exclusively to operations for the removal of the limbs, whether in their continuity or at their articulations.

I cannot agree with those who have denounced amputations as a disgrace to surgery; it is only when they are performed unnecessarily that they ought to be stigmatized by the profession and the public as an evil. Every pursuit is liable to abuse, to sins of omission and commission, and it would be strange if limbs were not occasionally cut off that might, under judicious management, have been saved. To denounce amputations, and to declare that they afford evidence only of the impotency and imperfection of our art, is to take a very narrow and erroneous view of the subject. It is not intended, so far as our own feeble powers of reflection enable us to comprehend the matter, that man should be able to cure every disease to which "flesh is heir." There are many maladies, as well as accidents, which are of necessity mortal; lesions which no human agency can repair or remedy. Who can save a limb that has been mangled and cut to pieces by the passage of a railway car, by the explosion of a steamboat boiler, by the fierce contact of a cannon ball, or by a fall from the top of a house down upon a heap of stones? Where is the surgeon that can prevent mortification from a burn that has charred the flesh, from a cold that has completely frozen the toes and feet, or from a malignant pustule that has inoculated all the tissues of an extremity? Is surgery to be held responsible because it cannot cure sarcoma of the bones, scrofula of the joints, and aneurism of the thigh and leg? So far from imputing blame to it, in these and similar cases, we should be grateful for the assistance which it is capable of affording us as a means of relieving suffering and prolonging life. It is under such circumstances, in particular, that we can best appreciate its great and inestimable value. If it were not for the merciful interposition here of the knife, such cases would inevitably be doomed to a rapid and miserable death. Mortification would speedily do its work, the sarcomatous tumor would steadily spread and finally ulcerate, forming a frightful, disgusting, and painful mass of disease, and the scrofulous joint would soon wear out the system by hectic irritation. It is a sad thing to lose a limb, but it is also a sad thing to die; and what rational being, if he could have his choice, would not rather part with an extremity than with his life? No humane, enlightened, and conscientious surgeon will ever resort to amputation without being satisfied of its entire and perfect necessity; if he is young and inexperienced, he will be sure to avail himself of the best counsel within his reach, while, if he is thrown upon his own resources, he will not fail to give the case all the consideration and reflection that his own knowledge, wisdom, and judgment may enable him to bring to his aid for

the relief of the poor sufferer whom he is obliged to mutilate in order that he may rescue his life from the dangers which threaten him.   I know of no operation which I approach with so much reluctance as the amputation of a limb, or one which gives me more real pain.   To cut off an arm at the shoulder on account of an incipient sarcomatous affection of the head of the humerus, when the elbow, forearm, hand, and fingers are all perfectly natural and glowing with health, unconscious, so to speak, of the fate which awaits them, is enough to sicken the stoutest heart, and to discourage the boldest operator. If there is a more disagreeable task than this, I am ignorant of it ; and yet I would not shrink from its performance even when there is but a faint prospect of prolonging life, if only for a few months.   But the case is different, widely different, when the surgeon is called upon to amputate a limb crushed and lacerated by machinery ; here there is no choice, no question concerning a cure by mere therapeutic measures ; the knife is the only remedy, and the sooner it does its work the greater, as a general rule, will be the patient's chance of recovery.   The body, it is true, is mutilated, perhaps sadly disfigured, but life is safe, and surgery, science, and humanity have achieved a real triumph.   So long as there are accidents and diseases incurable by medical treatment, so long will there be a necessity for amputation, and happy is he who shall know when and how to perform it to the best advantage for his patient and the greatest credit to the art and science of surgery.

SECT. II.—CIRCUMSTANCES DEMANDING AMPUTATION.

The circumstances for which amputation may be required are not only numerous, but extremely diversified in their character, and, therefore, deserving of the most careful consideration.   They may be comprised under the following heads :—1. External injury, as wounds, fractures, and dislocations.   2. Mortification, however induced.   3. Morbid growths.   4. Aneurisms.   5. Diseases of the bones and joints.   6. Intractable ulcers. 7. Malformations and deformities.   8. Tetanus.   The topics here enumerated comprise almost every kind of morbid action that can arise in the animal economy, and it will be perceived that they afford a wide and complicated field for the exercise of the talents and judgment of the surgeon.   Space will not permit me to enter as fully into their details as might, perhaps, be desired ; but I shall endeavor to advert briefly to the more important facts included under each head, having already called attention to some of them in the chapters on gangrene and wounds.

1. *Injuries.*   There are no lesions for which amputations are so frequently required as for wounds, fractures and dislocations.   Although they differ widely from each other in regard to the nature of the structures involved, these injuries may all be very properly classed under the same head, the more especially as they often coexist, thus rendering it difficult to determine which of them is the most serious.

Of wounds, properly so called, the only ones which require to be considered in connection with the present subject are the lacerated, contused, gunshot, and railway.   Wounds inflicted by rabid animals occasionally, it is true, demand amputation, particularly when they extend deeply among the bones, as in the hands and feet ; but even here complete riddance may generally be easily effected by a careful excision of the bitten parts, and the cauterization of the raw surface after the cessation of hemorrhage.   I should certainly hesitate to cut off an arm or a leg in such an event ; with the knife and saw I should expect to accomplish all that was necessary, in any case, for the safety of the patient.

Lacerated wounds, as well as contused and gunshot wounds, of a most frightful, and, at first sight, apparently of the most desperate character, are sometimes recovered from in an extraordinarily short time, and with hardly any untoward symptoms.   On the other hand, experience shows that the most insignificant injuries of this kind occasionally prove fatal in a manner and under circumstances which render it extremely difficult to account for the result.   It would be fortunate, both for our patients and for the interests of science, if we could always form, if not a positive, at least an approximate, estimate of the danger involved in each particular case of these wounds, for then it would be comparatively easy to adopt a suitable plan of treatment ; but, as it is, much must be left, in every instance, to the experience and judgment of the practitioner.   In general, however, it may be observed that all such wounds are fraught with danger, both to limb and life, when they are attended with extensive laceration of the soft parts, when the muscles have been horribly bruised and pulpified, important nerves cut across, the principal arteries, or arteries and veins, torn open, large joints penetrated, and the bones broken in pieces.   Under such circumstances there is not even a "forlorn hope," no matter what may have been the

previous health and habits of the sufferer; the knife is required, and the sooner it is employed the better. Such cases are absolutely desperate, and no one who has any knowledge of consequences can hesitate as to the course to be pursued. Upon this point there is no discrepancy of opinion whatever among surgeons. But the injury may be of a less severe character, involving, it may be, merely a considerable contusion of the soft structures with a compound fracture; or several muscles may be badly lacerated and the principal artery of a limb cut across; or a large nerve, the main trunk, perhaps, be divided, or the interior of a large joint exposed. The case now assumes a more trying aspect; the responsibility falls upon the surgeon with tenfold force; for the question naturally and at once arises, What shall be done? Shall such a limb be immediately amputated, or shall an attempt be made to preserve it? This is a question which will probably be asked by the patient himself, or by his friends for him, and which it is often extremely embarrassing and difficult to answer; in fact, it can only be answered upon general principles in one sense, and upon special principles in another. Looking at such injuries in a general manner, we might be inclined to give a favorable prognosis, because it is undoubtedly true that recovery from such lesions is by no means uncommon; but when we come to examine into the particulars of the case, we might not regard it in so auspicious a light. Thus, for example, the patient's antecedents may all have been bad, perhaps of the worst possible description; intemperance and dissipation of various kinds may have undermined his constitution, and thus rendered it unable to bear up under an injury which he would formerly have supported without difficulty; or, instead of this, there may be serious structural disease of some vital organ, as the heart, stomach, or lungs, disqualifying him for enduring the accidental and now heavy burden. All these circumstances must have their weight with the practitioner when he sits in judgment respecting the propriety or impropriety of an amputation. Conservative surgery may and does do much, but it cannot do everything; it has its limits, beyond which it cannot safely go, and there are many points which require to be considered in order that it may do itself justice. A very severe injury, occurring in a stout youth, of healthy constitution and temperate habits, is often promptly recovered from, while less than one-third of its amount, in a sickly, anemic, or dissipated person, will frequently destroy life in a few days; or, at all events, so far endanger it as to cause great anxiety for the result.

Gunshot, railway, and steamboat accidents, and injuries occasioned by the caving in of stone quarries, are extremely liable, if an attempt be made to save the limb, to be followed by the worst results; and, what is particularly embarrassing, in these cases, is the difficulty which the practitioner often has to encounter in ascertaining the precise amount of the lesion. The limb, perhaps, is entirely free from contusion and wound; or, if there be any injury of this kind, it may be so slight as to be regarded as of no consequence. The mischief is deep-seated, and, upon careful examination, it will, probably, be found to involve nearly every important structure, muscle, tendon, aponuerosis, vessel, nerve, bone, and joint. Such cases obviously require the closest scrutiny with a view to the speedy detection of their true nature and their proper mode of management. Generally the limb is so hopelessly injured as to require removal.

Compound fractures and dislocations, and gunshot wounds of the joints, often require amputation, and yet it is remarkable how the parts and system sometimes bear up under such injuries, especially in young and healthy subjects. Under the improved methods of management of modern surgery recoveries occasionally occur, which, in former times, when their treatment was less perfectly understood than it is now, would have astonished the practitioner. In this country the treatment of compound fractures and dislocations by occlusion, thereby converting these lesions into simple accidents, and of the former by extending and counterextending bands of adhesive plaster, has greatly contributed to this result. The danger of these injuries is much greater, other things being equal, when they occur in the inferior extremity than when they are situated in the arm and forearm, and in all cases the risk is much increased when they are accompanied by an open state of an important articulation, as that of the hip, knee, or ankle. Compound fractures in the continuity of a limb, unless complicated with serious lesion of the soft structures, do not generally require amputation; if judiciously managed, they will usually get well without much trouble. Gunshot wounds, occurring in civil practice, are commonly less dangerous than injuries of this kind happening on the field of battle or on shipboard. I have seen enough of the former of these accidents to satisfy me that the patient will often recover with a very good limb, even when there has been extensive loss of substance and great comminution of the bones. In military practice, on the contrary, there will often be much difficulty in preserving the parts, simply because it is frequently impossible to

treat the case properly on account of the want of suitable accommodations and a salubrious atmosphere.   It is for these reasons that amputation is so often resorted to, during and after engagements, in cases which, if they took place under ordinary circumstances, could be successfully managed by milder means.

When amputation is determined upon, in these and similar accidents, the next question is, when should it be performed?   Should it be done immediately, or should the surgeon wait until the system has recovered from the shock of the injury?   To use the knife while the patient is in an exhausted, pallid, and, perhaps, almost pulseless condition, would only serve the more certainly and effectually to seal his fate ; the additional shock to the constitution from the loss of blood and nervous fluid could hardly fail to prove most disastrous.   Hence the rule is to postpone a resort to the knife until there is satisfactory evidence of reaction ; until, in a word, warmth and color return to the surface, the pulse beats vigorously at the wrist, and the sufferer regains, in some degree, his consciousness and courage.   Now the use of an anæsthetic is well borne, and the limb is removed with comparative impunity.   On the other hand, care is taken not to wait until the part and system are assailed by inflammation, which, under such circumstances, often extends with frightful rapidity, placing the case, perhaps, literally beyond the resources of surgery in the course of a few hours.   There is, therefore, a time when interference must be avoided, not less than when it must be courted.   The limits of these two periods are not always well defined, and must, therefore, be left, in each individual case, to the judgment of the attendant.

An amputation, performed immediately after the occurrence of reaction, is usually designated by the prefix "primary," while the term "secondary" is used to denote the operation when it is executed after the limb has passed through the different stages of inflammation, an attempt having been made, perhaps well grounded, so far as the interpretation of the symptoms is concerned, to save the parts.   Such a contingency must necessarily happen rather frequently, especially in civil practice ; indeed, it is often altogether unavoidable on account of the obstacles interposed by the patient and his friends, independently of the wavering and indecision of the professional attendant.   But, although often unavoidable, such an occurrence is always much to be regretted ; for if the chances of saving limb and life were bad in the first instance, they are now generally much worse ; the system has been impaired by fever and perhaps hectic irritation, the secretions are seriously deranged, the patient has little appetite and sleep, the blood is thin and watery, and the whole body is much emaciated.   Life may possibly still be preserved, but the probability is that the operation will be attended with much risk, and that ultimate recovery is far off.   Moreover, a much larger amount of limb may now have to be sacrificed ; originally a foot might have sufficed, whereas now, in consequence of the ravages of the inflammation, the whole leg may require removal.   There is, then, obviously, an advantage in a primary over a secondary amputation, provided it is performed at the proper time, that is, after the establishment of reaction and before the occurrence of inflammation ; and this circumstance is often eagerly embraced by the military surgeon, whose will is always law with his patients.

In addition to these divisions, some writers speak of what they term an "intermediary" amputation, performed immediately, or soon, after the supervention of inflammation, and, consequently, before the establishment of suppuration.   This distinction was first made by Bucher, in the last century, in a memoir addressed to the French Academy, and was subsequently adopted by Guthrie, Alcock, and other military surgeons, in the early part of the present.   Such an amputation is unquestionably the very worst that can be selected, inasmuch as it is performed at a period when the part and system, assailed by inflammation and fever, are ill able to bear up under its effects.   Hence the mortality must necessarily be much greater than after either of the other procedures ; and yet it is easy to perceive that cases might arise, both in private, hospital, and military practice, where it would be perfectly unavoidable.   Accidents, as gunshot, railway, and other injuries, of the very worst character, must often occur under circumstances in which the patient is either neglected, or where it is impossible to remove the mutilated parts before the occurrence of inflammation and symptomatic disturbance.   The moment the surgeon sees the case it is obvious at a glance that amputation is necessary ; there is no other chance for the patient's life ; nor is any time to be lost.   Mortification is either impending or has already taken place, and in a few hours the case may be wholly beyond the reach of the knife.   Here there is no choice.   Operative interference is compulsory and imperative. In estimating the mortality of primary and secondary amputations it is very important to exclude the intermediary, otherwise the calculations must lead to error.

2. *Mortification.*—Mortification, in whatever manner induced, necessarily imperils limb and life, and, therefore, often becomes a subject for amputation. Hence the question arises, under what circumstances is a resort to the operation advisable and proper? This question can only be answered satisfactorily by a consideration of the nature of the mortification. In the chapter on mortification will be found an account of the several varieties of this affection, the causes under the influence of which they take place, their symptoms, and the means required for their relief. By a reference to that portion of the work, it will be seen that, as it respects the operation under notice, the great rule, recognized by nearly all practitioners at the present day, in acute gangrene, is, to wait for the formation of a line of demarcation between the dead and living parts, on the ground that it is not generally safe to interfere sooner, lest the disease should reappear upon the stump, and thus destroy the patient, or necessitate a repetition of the amputation. Of the propriety of this rule there can be no question, for there is no surgeon of experience who has not witnessed its beneficial effects in his own practice, as well as in that of his friends, and yet it is equally true that it may occasionally be violated with great advantage. But I would apply to these cases the term "exceptional," comprising under this head those attacks of mortification which are so liable to supervene upon inflammation from external injury, as wounds, fractures, and dislocations, which often spread with immense rapidity, hopelessly overwhelming, if they are not promptly arrested, both the part and system in a few hours. It will not do for the surgeon, in such an emergency, to fold his arms and become an idle spectator; he must have his eyes and wits about him, or his patient will be irretrievably lost; whatever is done must be done quickly. The wished-for line of demarcation will be looked for in vain; the gangrene will rapidly extend to the trunk, and death must soon close the scene. But in spontaneous mortification, or in mortification from erysipelas, carbuncle, and analogous affections, the judicious surgeon waits for the arrest of the morbid action, his chief care being to bring about this event as speedily as possible by appropriate local and constitutional measures. His rule of action is the same in hospital gangrene; in both cases means are employed for supporting the system, or, what is equivalent to the same thing, for improving the condition of the fluids and solids, and the knife is used only when the line of circumvallation is fully established, not a minute before.

In senile, chronic, or dry gangrene, the result usually of calcification of the arteries and of their occlusion by fibrinous concretions, thus depriving the tissues of their due supply of blood, the rule has heretofore been to wait for the cessation of the mortification, experience having shown that, when this precaution is neglected, the disease will be certain to reappear in the stump. It is in view of this relapsing tendency in mortification that some surgeons, of great eminence and experience, have given it as their judgment that the case should always be left entirely to nature's efforts; in other words, that we should wait for spontaneous amputation, shaping the stump after the sloughs have been nearly completely detached, when, it is alleged, the part and system will be better prepared to withstand the shock of the knife. The propriety of such advice is sufficiently obvious when it is considered that this disease occurs nearly always in very old and infirm subjects, and that it is essentially dependent upon obstruction of the arteries leading to the affected structures. Such individuals, as I know from personal observation, are usually very feeble, and, consequently, ill able to resist the effects of shock or loss of blood. They often rapidly sink after the operation, even when there has been a distinct line of demarcation; or, if they survive its immediate effects, the disease speedily reappears upon the stump, and soon destroys life secondarily. When we reflect how common these events are, would it not be wise, in these cases, to amputate early at a great distance from the disease, before the vital powers have been seriously assailed by the morbid action; to remove, for instance, the limb at the knee, for senile or chronic gangrene of the toes and feet? The only objection to such a procedure, it seems to me, would be where the occlusion of the main artery of the limb reaches above this point. When no such disease exists, and the general health has not materially suffered, I should not hesitate to resort to the expedient, under the conviction that, however severe, it was perfectly justifiable in a class of cases so unpromising as this confessedly is.

3. *Morbid Growths.*—Amputation is sometimes required on account of morbid growths or tumors, both benign and malignant. The removal of the forearm is perfectly proper for the cure of sarcoma of the hand, and of the arm at the shoulder for a similar affection of the humerus. A similar rule is applicable to the inferior extremity. Half-way measures here, as elsewhere, are worse than useless. To amputate in the continuity of

the thigh when the lower part of the limb is affected with a malignant growth would be a blunder and a crime. No operation is of course admissible if there be marked constitutional involvement, enlargement of the neighboring lymphatic glands, or decided tendency to ulceration; the propitious period has gone by, and interference would only hasten the fatal event. It is not so, however, so long as the health remains good, and there is no evidence of general or local contamination; under such circumstances there is a strong probability that removal of the limb, although it may not prevent a recurrence of the disease, may yet considerably prolong the patient's life.

A tumor, wholly divested of malignancy, may, in consequence of acting obstructingly, cause so much functional and other disturbance as to demand removal of the limb upon which it is situated. The procedure will be particularly called for when the morbid growth is intimately connected with a bone, or deeply and inseparably involved in the soft parts, or prolonged into an important joint, compelling free exposure of its surfaces during the operation. A valuable rule in tumors is to excise the benign, and to get rid of the malignant by amputation.

4. *Aneurism.*—A neglected aneurism, seated in an extremity, and unamenable to ordinary treatment, occasionally calls for the removal of a limb; in former times such operations were sufficiently frequent when the disease occupied the popliteal region, though at present they are seldom, if ever, required, except when mortification sets in after ligation of the femoral artery, or from the injurious compression exerted by the tumor upon the leg.

5. *Affections of Bones and Joints.*—Various affections of the bones and joints, as caries, necrosis, morbid growths, tuberculosis, and ankylosis, may impose the necessity of amputation; and there is, according to my experience, no class of diseases in which the operation has been more frequently abused or misapplied. There can be no question that many a limb, merely temporarily crippled by remediable disease, has been ruthlessly sacrificed to ignorance and a desire for eclat: carious joints, now that excision has been revived, can seldom demand so harsh a procedure, and as to necrosis, pure and uncomplicated, it is difficult to conceive of a case justifying the use of the knife. It is only, or mainly, in white swelling, or scrofulous disease of the knee, ankle, and elbow, attended with hectic irritation, excessive pain, and exhausting diarrhœa, that the removal of a limb can be proper, and even then it should not be thought of if it be possible to exsect the affected structures without imperilling life by shock and loss of blood. In whatever manner the offending parts are disposed of, it is surprising to witness the great improvement which usually follows the operation; the profuse sweats and alvine discharges rapidly disappear, the appetite improves, the sleep becomes refreshing, and the patient soon regains his flesh and strength. Unfortunately, the operation is generally put off to an unreasonable period, so that, when it is at length performed, the sufferer too frequently sinks under its effects.

Of malignant growths of the bones almost the only primary one demanding amputation of the limbs is sarcoma. When epithelioma of the skin extends to the osseous system, as sometimes happens, the same treatment must be applied to it as to sarcoma; that is, early and thorough removal by the sacrifice of the suffering extremity. Temporary relief only, as a rule, is aimed at; sooner or later the disease recurs, either at the cicatrice, or in some neighboring organ, and carries off the patient.

Fibrous, cartilaginous, and osseous growths involving the bones sometimes constitute a legitimate ground for amputation. An exostosis, of enormous size, and grotesque form, may render an extremity not only perfectly useless, but a source of the greatest inconvenience and even suffering. Pulsating tumors of the osseous tissue, met with chiefly in the head of the tibia, nearly always demand the same remedy.

Finally, amputation may be required on account of ankylosis of a joint, interfering with the comfort and usefulness of an extremity. Thus, in ankylosis of the knee, the leg may stand off at a right angle with the thigh, so as to interfere materially with the occupation of the individual, and induce a wish for an artificial limb, which, if well constructed, is generally worn with great satisfaction. Stiff and crooked fingers and toes are often the subjects of amputation.

6. *Ulcers.*—Amputation is sometimes performed on account of old and inveterate ulcers of the extremities; the operation, however, is less frequently resorted to now than formerly, and might, with proper management, be almost entirely dispensed with. Unless the sore is of a carcinomatous character, or caused by burns, scalds, or frost-bites, or complicated with serious lesion of the bones, excessive enlargement of the veins, or great

hypertrophy of the integument, there are few cases, it seems to me, that will not gradually yield to judicious treatment. Of the numerous ulcers of the extremities that have fallen under my observation, embracing, of course, many of the worst description, I have a distinct recollection only of three that required this harsh measure. Whether other practitioners have been equally fortunate I am not able to state ; but, judging from the reports of cases in our periodicals, it is highly probable that the operation is still not unfrequently performed on this account.

7. *Malformations.*—There are certain malformations and deformities for the relief of which amputation may be demanded. An irremediable clubfoot, especially if complicated with a painful bunion, an intractable ulcer, or excessive atrophy of the leg, would form a proper subject for such an operation ; for there are few men who would not rather run the risk attending its performance than to be incessantly fretted and worried by such a disagreeable and useless companion. Supernumerary thumbs and fingers are disposed of in a similar manner ; the operation is usually done within a few months after birth, and I have never known it to be followed by any bad consequences. Amputation is occasionally necessary on account of deformity caused by burns and scalds, or badly treated fractures and luxations.

8. *Tetanus.*—The propriety of amputating in tetanus has been so long doubted by many of the highest authorities in surgery that the question hardly merits serious consideration in a work of this kind. I have certainly not seen anything in my own practice tending to contradict an opinion now almost universally entertained by the profession in this and other countries. If such a measure is ever justifiable, it must be at the very commencement of the disease, before the supervention of the characteristic symptoms. I have seen a very considerable number of instances of acute traumatic tetanus, and, with a few solitary exceptions, they have all proved fatal. One of the cases was that of a stout, well-fed countryman, fifty years of age, the fore and middle fingers of whose right hand had been badly crushed by the passage of the wheel of a wagon ; symptoms of tetanus came on upwards of a month after the accident, and, although the disease had existed for five days when I amputated at the metacarpo-phalangeal articulation, yet complete recovery followed, not, however, without a slight continuance of the spasms for a short time after. In another case the little finger of the left hand had been crushed a fortnight previously, and I amputated it the morning after my first visit. Although the symptoms had all day been very severe, a gradual improvement soon became apparent, and the patient, a young man, twenty-four years of age, made an excellent recovery. The principal remedies were saturnine and anodyne lotions, quinine, morphia, and milk punch in liberal quantities. I presume a practitioner would hesitate to cut off a large limb after the development of tetanus under any circumstances ; for, whatever notions may be entertained respecting the pathology of this affection, there can be no doubt that, once fully established, it must be looked upon as a constitutional disorder in the widest sense of that term.

SECT. III.—METHODS OF AMPUTATION.

Two principal methods are in vogue for performing amputation of the limbs, whether in their continuity or at the joints. These are the circular and the flap, both of which, but especially the former, are of ancient date, and therefore well grounded in the esteem of the profession. To these was added, early in the present century, the oval operation, which, although excellent in its way, has hitherto received but little attention ; certainly less than it deserves. In 1855, an operation, termed the rectangular, was also proposed. At present, flaps constructed entirely of integument are much in vogue. It is not my object to enter into the history of these different methods, for to do so would carry me back into the regions of doubt and speculation ; but it will be expected that I should offer some remarks concerning their respective advantages and disadvantages, and this I shall endeavor to do in as concise and impartial a manner as may be consistent with the great interest and importance of the subject.

1. *Circular Method.*—The circular operation, the most ancient of all, was originally performed in the most simple manner, the integument, muscles, and bones being all divided upon the same level. The consequence of this procedure was that the bones, inadequately covered by the soft parts, or, rather, not covered at all, invariably perished to the distance of several inches, thus sadly protracting the cure, besides subjecting the patient to much suffering and not a little risk in the interval. As surgeons became more

enlightened, they endeavored to provide against this contingency by forcibly pulling back the muscles, by means of a peculiar contrivance called a retractor, before using the saw, which was then applied close to the surface of the tissues. At a later period still, and as a decided improvement upon the preceding methods, arose the plan of double incision, devised by Cheselden, better known for his success as a lithotomist than for his exploits as a general operator. It consisted, as, indeed, the name sufficiently indicates, of two stages, in the first of which the integument was cut and drawn back, while in the second the muscles were divided higher up, the object being to afford more thorough protection to the bone. The operation of the English surgeon has undergone various modifications, some of which, having only served to render it more complex, have been justly discarded from practice. To this category belong the division of the muscles by two circular incisions, one higher up than the other, and the plan of scooping out the parts as the knife was being swept obliquely around them by cutting from below upwards and from without inwards towards the bone, which thus formed the apex of the hollow cone.

The circular operation, as now generally practised, consists, first, in dividing the common integument, dissecting it from the parts beneath, to a variable extent, and then drawing it back, or even turning it up like the cuff of a coat; secondly, in cutting through the muscles on a level with the retracted skin, and, after detaching them for some distance from the bone, holding them also forcibly back; and, thirdly, in sawing off the bone as high up as possible without doing violence to the soft structures. In executing these several stages of the proceeding, a long amputating knife, poised lightly between the thumb and fingers, is carried rapidly around the limb, the point being inserted into its anterior surface, external to the middle line, and thence drawn towards the operator in such a manner that the heel of the instrument shall finish the incision. The wound thus made extends simply down to the aponeurosis, and care should be taken that it occupies the same level throughout, unless there be special reasons for carrying it higher or lower at one point than another, rendered necessary, it may be, by the presence of a vicious cicatrice, ulceration, gangrene, or some morbid growth. The flap is then rapidly dissected up, either with the same instrument or with a large scalpel, and held out of the way, its length being regulated by the thickness of the limb, about two inches and a half being a good average. The amputating knife being now resumed, and held as before, is applied closely to the edge of the retracted integument, and then drawn around the member so as to divide all the muscles down to the bone, as represented in fig. 207. This part of the

Fig. 207.

Circular Amputation shown in the Leg, the Integument being turned back, and the Muscles divided down to the Bones.

operation is usually the work of a few seconds. The next step is to separate the muscles carefully from their connection with the bone, to the distance of at least an inch and a half, if not more, when, being pressed forcibly back by means of a retractor, the bone is sawed off close to their surface. The adjoining cuts, figs. 208 and 209, afford a good illustration of the appearances of the limb, both below and above the stump, after this operation.

In sawing the bone, whether in this or in the flap operation, it is an object of primary importance to inflict as little injury as possible upon the periosteum; for the less the integrity of this membrane is disturbed the less likelihood there will be of necrosis, myelitis, and other bad consequences. When the periosteum is very thick, as in the thigh-bone, a circular track may be made in it for the saw, to lessen the risk of laceration. The value of the practice of saving a sufficiency of periosteum to cover in the extremity of the bone, followed of late years by certain operators, is not as yet fully determined. The object is to protect the medullary canal against the entrance of pus and other fluids, thereby preventing the occurrence of osteomyelitis, pyemia, and other mischief. Much might certainly be said in favor of the procedure, which, however, is not, by any means, always easy of execution. In every instance the utmost care should be taken to injure this membrane as little as possible with the saw.

The manner of dividing the bone is a matter of some moment. In most of the amputations that I have witnessed the instrument was applied against the front of the bone, instead of being held perpendicularly so as to divide the bone from side to side, as it generally should be to avoid fracture, which is so liable to happen if proper care be not taken to support the limb in this stage of the procedure. Particular rules are usually laid down
by authors for working the saw. Thus, it is generally stated that the heel alone of the instrument should be used until a sufficient track is made for it; but I consider all such directions as unnecessary, if not frivolous. If the saw is properly set, it is of little consequence, according to my experience, what part is applied first or last, or whether it is moved

Fig. 208.　　　　　　　　　　　　　　　Fig. 209.

Fig. 209.—Appearance of the Stump in the Circular Amputation.

rapidly or slowly, although, as a matter of choice, I should prefer to finish the operation as quickly as possible. When there are two bones of equal size to be cut, as in amputations of the forearm, they should be divided simultaneously; but if one is thicker than the other, as in the leg, the weaker must always be severed first, lest, if it remain until the other is sawed through, it should be broken or splintered, and so impose the necessity of employing the nippers to smooth its extremity.

When a limb is removed at a joint, the best plan, as a general rule, is to dispense with the use of the saw and the pliers altogether, experience having shown that the preservation of the articular cartilages greatly favors the adhesive process, and thereby expedites the cure. Sawing off the ends of the bones exposes the parts to suppuration, erysipelas, caries, necrosis, and even to the danger of pyemia.

2. *Flap Method.*—Although the flap operation was described, and no doubt practised, by some of the earlier surgeons, it does not seem to have received any particular attention until towards the close of the seventeenth century, when Lowdham, of Oxford, England, published a short tract upon it, setting forth its advantages over the circular method. After this period it was occasionally performed in different parts of Europe, especially in France and England, but it never fully acquired the confidence of the profession until the time of Mr. Liston, whose teachings and writings brought it into general notice.

There are several methods of forming the flaps, the choice of which must be regulated by the particular circumstances of each individual case. Thus, the operation may be performed by transfixion of the limb, and cutting from within outwards; by commencing at the surface, and carrying the knife inwards towards the bone; or, lastly, by making one of the flaps after the former fashion, and the other after the latter. In amputations of the thigh and arm, it is customary to make both flaps by transfixion, as the operation is thus greatly simplified and rendered more expeditious; but in the forearm, hand, fingers, leg, foot, and toes, they are formed either by cutting inwards, or one by cutting inwards and the other by cutting outwards. The number of flaps varies; in general there are two, but occasionally there is only one, and, on the other hand, there may be as many as three; accident, or the situation and structure of the limb, rendering one of these modes preferable to another. Thus, in one instance, I amputated the thigh at its middle by a solitary flap, and succeeded in effecting an excellent cure. The military surgeon is often compelled to form his flaps as best he can, owing to the manner in which the soft parts are injured, and in civil practice the same difficulty sometimes occurs in consequence of the effects of disease or accident. Whatever may be the nature of the case, the rule is never

to include any unsound tissues or any portion of bone that is fractured or divested of periosteum. In amputating the thigh and arm at their middle, the flaps are generally cut of the same length; but in most other situations one is usually made considerably longer than the other, depending upon the greater amount of muscular substance. Their relative length must be regulated by the thickness of the limb, and the quantity, laxity, and contractility of the soft parts. It is better, in every case, to have too much substance than too little, but the judicious surgeon will always endeavor so to cut his flaps as to have just enough, and no more, to form a well-shaped and useful stump, redundancy being always unseemly, if not actually in the way of comfort and convenience. As a general rule, their length should equal about three-fourths of the diameter of the limb, being invariably greater than in a similar operation upon the dead subject, to allow for contraction and shrinkage. The form of the body of the flaps is commonly somewhat convex, while the extremity is more or less oblique, care being taken that they do not terminate in thin, narrow ends, and that there is always an abundance of integument after they are adjusted over the bone. When the muscular tissue is unusually abundant, as often happens in amputating through the calf of the leg, I have found it advisable to retrench it with the knife, in order to give the stump a more seemly shape, as well as to place it in a better condition for bearing the pressure of an artificial limb.

In performing the operation the same general rules are to be observed as in the circular method; hemorrhage is restrained by the same means, and the skin is drawn back by the hands of an assistant, who also retracts the flaps as one after the other is formed, and thus holds them out of the way of the knife and saw. Any important vessels that may be bleeding are instantly compressed by the fingers until they can be tied. Before applying the saw, the knife is passed closely around the bone so as to divide every muscular fibre, and also, if possible, the periosteum. The most suitable instrument for removing the larger limbs is a long amputating knife; for the smaller ones, an ordinary scalpel, bistoury, or catlin will answer best. Separation of the member having been effected, and the vessels carefully secured, the next thing is to cut off the principal nervous trunks a little above the level of the surface of the stump, and, as the operation is one of excessive pain, it should always be performed before the patient has fully recovered from the

Fig. 210.   Fig. 211.

shown in the Amputated Part.

influence of the anæsthetic. I need not dwell upon the importance of thus dealing with the nerves involved in the flaps; the necessity of the procedure must be obvious upon the slightest reflection. When it is considered that they always become more or less enlarged and bulbous after all operations of this kind, it is easy to perceive what would be the consequence if they were brought in contact, as some of them almost inevitably would be, with the extremity of the bone, before it has had time to become rounded off. I regard no amputation by the flap method as being finished unless provision has been made against such a contingency. The adjoining cuts, figs. 210 and 211, represent the appearance of the stump and of the limb after its removal.

3. *Oval Method.*—In the oval method, as it is termed by Scoutetten, by whom it has been generalized, or the oblique process, as it has been called by others, the wound has somewhat of the shape of an ovoid, the small extremity of which corresponds to the bone or joint which is the seat of the amputation. The operation holds a kind of intermediate position between the other two, resembling the circular process in the mode of incising the soft parts, and the flap in the form of the wound. It is principally adapted to amputations of the joints, particularly the smaller, as, for example, the metacarpo-phalangeal, but it has also been applied to the joints of the hip and shoulder, especially by Guthrie, Larrey, and Scoutetten, who have devised plans which severally bear their names.

In the oval operation the flaps are formed by cutting from without inwards, or one is formed in this way and the other by cutting in the opposite direction, or from within outwards. It is commenced by making two incisions in the shape of the letter V reversed, the angle of union falling a little above the place where it is intended to saw the bone or effect disarticulation. These incisions are, of course, extended as far as the periosteum, when the knife, drawn closely around behind the bone, is carried downwards on a level with the termination of the two cuts already made, thus connecting them by one thrust, as the instrument sweeps through the intervening tissues. By adopting this plan of procedure the surgeon will have it in his power to leave the principal vessels and nerves until the operation is nearly completed, a circumstance which thus affords him a much better control over the hemorrhage.

The oval operation usually makes an excellent stump, there being always an abundance of material for covering the bone : it is generally a little more tedious than the flap amputation, but this should not be urged as an objection to it, as in all other respects the result is most satisfactory.

4. *Rectangular Method.*—Mr. T. Pridgin Teale, of Leeds, in 1855 modified the double flap operation by substituting a long and a short rectangular flap. The long flap should be made from the portion of the limb which does not contain important bloodvessels and nerves, these being included in the short one. Before proceeding to the operation, the lines of the incision should be traced with ink, in order to insure the proper dimensions of the large flap, which should be equal, in length and breadth, to one-half the circumference of the limb at the point amputated. Thus, for example, if the circumference of the limb be nine inches, the length and breadth of the flap should each be four inches and a half. The short flap, which should be made last, must be one-fourth the length of the long one. The lines of the incisions and the length of the flaps will be more easily understood from the annexed cut, fig. 212, representing an amputation of the thigh. The parts

Teale's Operation, the Flaps being Drawn
Together.

having been dissected off, in close contact with the periosteum, the long flap will be found to be perfectly square, and to contain a sufficient amount of movable soft parts to form a complete cushion for the end of the bone, which must be sawed off perfectly straight, and must be free from spicules, in order to prevent ulceration of the soft structures. The arteries having been tied, and the larger nerves retrenched, as in the ordinary flap operation, the long flap is brought down over the end of the bone, and attached to the short one by several points of the interrupted suture. The short flap is also attached to the long flap laterally, as is also the reflected portion of the long flap to its unreflected portion. The dressing is completed by the application of a few narrow adhesive strips. The appearances of the parts, when brought together, are shown in fig. 213.

The rectangular operation makes an excellent stump, furnishing an abundant covering for the bone; but, although this is true, it possesses no advantages whatever in ordinary cases over the common flap amputation, and will, therefore, not be likely to meet with general adoption. If it has any superiority whatever, it is in amputation of the thigh, where, by admitting of a greater saving of bone, it diminishes the risk to life. Unless great care be taken in forming the flaps, and in superintending the after-treatment, there will be danger of non-union, if not also of sloughing, from inadequate nervous and vascular supply.

Mr. Teale, in 1861, published the results of 103 cases of rectangular flap amputations, of which 84 were cured, and 19 died, or in the ratio of 1 in 5.4. Of the whole number 35 were of the thigh, and of these 11 died; 37 were of the leg, with a mortality of 4; 14 of the arm, with 4 deaths; and 17 of the forearm, without any deaths. On comparing these results with those of other amputations, it will be seen that the mortality is very slightly in favor of the rectangular method. It should be added that all the operations were performed at the Leeds General Infirmary by Mr. Teale and his colleagues, Mr. Smith and Mr. Hey.

Mr. James H. Wharton, of Dublin, in 1868, proposed a modification of Mr. Teale's operation, by which the posterior flap is dispensed with, and the bone sawed off on a level with what in the original method would form the lower border of the short flap, the object being to save as much bone as possible. The modification thus proposed has found warm advocates in several Irish surgeons, as Stokes, Mapother, Macnamara, Mayne, and Kelly, all of whom have performed it with the most gratifying results. The chief objection alleged against it is the retraction of the soft parts at the back part of the limb, an occurrence which, so far from being an evil, can always be readily counteracted by proper attention during the after-treatment.

5. *Cutaneous Method.*—Flaps composed exclusively of tegumentary structure are now much in vogue, both in this country and in Europe, even in the larger amputations, as in those of the thigh, leg, and arm. The advantages claimed for them are, first, that, as no muscles enter into their composition, there is less danger of separation of the edges of the wound, and, therefore, a better chance of union by the first intention; secondly, deep-seated suppuration, so common in the ordinary processes, is less frequent; thirdly, the operation is not so often followed by caries, necrosis, neuralgia, and other serious accidents; and, lastly, as the skin, after the completion of cicatrization, is movable over the extremity of the bone, the stump is better adapted to bear the pressure of an artificial limb. The chief objections to the method are, first, the liability of the flaps to slough, especially in cases of injury, attended with more or less contusion; and, secondly, the danger that the stump may eventually become conical in consequence of the retraction of the muscles.

The flaps in this operation may be of equal or unequal length and width, according to circumstances. In some instances one is made quite large, and the other proportionally small, the former being drawn, like a curtain, over the extremity of the bone, as the long flap in the rectangular operation of Teale. In case of accident, three or even four flaps may sometimes be advantageously made; and occasionally, again, the surgeon is obliged to content himself with one, as when the skin is disfigured by a vicious cicatrice, when a chasm has been made in it by an ulcer, or when it has been encroached upon by a morbid growth. However fashioned, they should always embrace as large an amount of connective and adipose tissues as possible, otherwise, their nervous and vascular supplies being thus greatly diminished, there will be danger of sloughing. The length of the flaps must vary, of course, with the diameter of the limb at the seat of the amputation. In an amputation of the thigh in an adult of ordinary stature, it should not, on an average, be less than from three and a half to four and a half inches. The golden rule here, as in all similar operations, is to provide an abundant covering for the bone, a result which may be materially aided by dividing the muscles a little below its level. The stump, after the flaps have been approximated, should be carefully bandaged from above downwards, as a means of preventing retraction. In the after-dressings the flaps should be disturbed as little as possible, as it is all-important that they should speedily unite to the extremity of the bone, in the hope of thereby lessening the risk of the occurrence of osteomyelitis, erysipelas, abscesses, and other serious consequences.

SECT. IV.—OPERATION AND AFTER-TREATMENT.

The position of the patient and the surgeon, the number and duties of the assistants, and the character of the instruments, must necessarily vary in different cases and under different circumstances, and can, therefore, be pointed out here only in a general manner.

The patient should always, if practicable, be recumbent, as he will thus be much less liable to become faint, and at the same time bear the effects of the anæsthetic much better than when he sits up. He may, however, put himself in the latter position without any inconvenience during the amputation of a finger or toe, or even of the arm or leg, if he is courageous, and willing to dispense with chloroform, or to take ether in its stead. The limb, well shaved, is generally held horizontally, away from the table, one assistant retracting the integument, and another supporting the portion to be removed. To prevent the loss of blood, always a great desideratum in an operation of this kind, the limb in all large amputations, should be firmly constricted, either with an ordinary roller, or a gumelastic bandage, as originally suggested by Esmarch, extending from the distal extremity upwards, when the limb should be encircled by a Petit's tourniquet or an elastic band, so as to cause complete stoppage of the circulation. I have satisfied myself that the ordinary muslin roller, if properly applied, answers quite as well in preventing hemorrhage in these operations as the elastic bandage; while it is far less liable to cause serious constriction of the cutaneous capillaries and nerves, and hence less liable to be followed by gangrene of the skin at and around the stump, an effect which is sure to supervene occasionally upon the use of the elastic compressor. An anæsthetic having been administered, the operation is proceeded with in as rapid, orderly, and careful a manner as possible. When the amputation is performed high up near the trunk, the tourniquet or elastic band may sometimes be advantageously replaced by the hands of an assistant, who trusts either to his thumbs alone, or else makes the requisite pressure by means of the handle of a stout key, wrapped around with a piece of muslin. In separating a large limb, not less than five assistants are generally necessary; one for administering the anæsthetic, a second to see to the bleeding, a third to hold up the flaps, one to support the distal portion of the member, and a fifth to hand the instruments and sponges, and aid in securing the arteries. A smaller number will, of course, suffice for the removal of a finger or other insignificant part.

The different methods of amputation are described in the preceding section. The one which I prefer is that by flap, although a most excellent stump may also be made by the circular operation. The rectangular method is well worthy of attention, as the arrangement of the long flap not only thoroughly protects the bone, but, what is of great consequence, admits of ready drainage. The oval operation is admirably adapted to amputations at the joints and to resections of the bones.

My reasons for preferring the flap to the circular operation are, first, because it is more simple and easy of execution; secondly, because it generally affords a much better covering for the bone; and, lastly, because the patient experiences much greater comfort in wearing an artificial substitute.

During the sitting of the commission appointed by Surgeon-General Hammond, to report on the subject of artificial limbs, convened at New York, in 1862, upwards of a dozen manufacturers, then present, unanimously assured me that stumps made by the circular operation are, as a general rule, in every respect, inferior to such as are made by the flap method; that it is much more difficult to fit them with an artificial substitute; and that they are a great deal more liable to become chafed, irritated, and ulcerated. The results of my own observations strongly corroborate this statement. I was at much pains, by visiting some of our military establishments during our late war, to inform myself personally of the comparative merits of the two operations, and, from all that I witnessed, I am satisfied that the preponderance is vastly in favor of the flap method. Dr. R. J. Levis, in charge of the government hospital in this city for the cure of bad stumps, during our late war, bears similar testimony.

The principal instruments required for the operation are, for the larger limbs, a tourniquet, or Esmarch's apparatus, described on page 489, an amputating knife, a catlin, saw, and pliers, which are properly arranged upon a tray in the order in which they may be needed. For removing the fingers, hand, toes, or foot, an ordinary scalpel will commonly suffice. The tourniquet in general use is that of Petit, the construction and arrangement of which may be readily learned from the annexed sketch, fig. 214, a circumstance which, besides the fact that it is found in every cutler's shop, renders any formal description of it unnecessary.

The tourniquet of Petit has been modified by Mr. Tiemann, of New York, in such a manner as to concentrate a much greater amount of pressure upon the artery, at the same

time that it does not embarrass the venous circulation.   The pad is placed either horizontally or crosswise upon the vessel, and the strap, carried round the limb, is passed through

Fig. 214.

Fig. 215.

Tiemann's Improved Tourniquet.

Petit's Tourniquet.

the two side apertures in the metallic plate, after which the ends are drawn very tight, and fastened on the protruding hooks.   The arrangement of the different pieces of the instrument is seen in fig. 215.

Fig. 216 represents an arterial compressor devised by me in 1856, as a convenient substitute for the ordinary tourniquet, over which, I conceive, it possesses several decided advantages; first, in the facility of its application; secondly, in the amount of pressure which it is capable of exerting; thirdly, in its ready adaptation to limbs of different dimensions; fourthly, in the circumstance that it makes pressure only at two points, that is, over the artery, and at the spot immediately opposite to the artery; and, lastly, the facility with which it may be slackened or removed at any stage of the operation.   With a little modification, the instrument may readily be adapted to the femoral artery as it emerges from beneath Poupart's ligament, or even to the external iliac just above this ligament, in amputation at the hip-joint, and also to the axillary artery, in disarticulation of the shoulder-joint.

Fig. 216. .

Artery Compressor.

The instrument, as will be seen by reference to the cut, is composed of two blades, differing in the degree of their curvatures, united by a screw, and regulated by a ratchet. Each short blade is provided with a pad, controlled by a screw, and designed to rest upon the artery which it is intended to compress.   By this arrangement two tourniquets are formed : a large one for the thigh, and a small one for the arm, or the thigh of a small subject.

The ordinary amputating knife, fig. 217, is from nine to twelve inches in length, by about five lines in width, with a moderately thick back, spear-pointed, and furnished with a stout, rough, ebony handle, to prevent it from dropping out of the hand if it should become smeared with blood.   The principal edge should extend the whole length of the blade, and be in the best possible condition for executing its important office, well tempered, and perfectly sharp.   The edge upon the back should not be longer than an inch and a half.   With such an instrument, properly managed, nearly all the amputations of

the body may be performed with great neatness and celerity. The catlin, shown in fig.
218, is a double-edged knife, used principally in removing the forearm and leg, and for

Fig. 217.

Amputating Knife.

dividing the interosseous muscles and ligaments : I cannot see, however, that it possesses
any special advantage, even in these cases, over the larger knife just described.

Fig. 218.

Catlin, or Double-edged Knife.

Every amputating case contains a large saw, resembling the common dove-tail saw of
the cabinet-maker. The adjoining sketch, fig. 219, represents the form of the instrument,
which I am myself in the habit of using. The blade, which is very firm, is ten inches
and a half in length at the cutting edge, by two inches and one-eighth in breadth, exclu-

Fig. 219.
Amputating Saw.

sive of the back, which is very thick and convex, in order to afford the proper degree of
strength which such an implement should always possess. The handle is rough, and
sufficiently large to receive two fingers, while the thumb and forefinger are applied to its
surfaces, parallel with the upper border, to keep it steady while engaged in the discharge
of its duty. The teeth are rather large but sharp, and set crosswise on the edge, that the
instrument may not hang or hitch as it works its way through the bone. The manner of
using the saw has already been described. What is known as Butcher's saw, represented
in the chapter on excision, is now generally put up in our amputating cases, and is by
many surgeons preferred to the saw there described. It is certainly a very excellent
instrument.

A small saw, such as is represented in fig. 220, will be of great service in amputations
of the hand and foot.

Fig. 220.

Small Amputating Saw.

Cutting pliers, fig. 221, of various sizes and forms, must be at hand; they should be
short but rather slender in the blades, and very long and strong in the handle. Although
I never use these instruments when it is possible to employ the saw, on account of their
tendency to bruise the osseous tissue, yet they are of great convenience for removing sharp
spicules, and cutting off certain pieces of the skeleton, as the phalanges of the toes and
fingers, the ribs, and the jaws.

The limb being removed, and the nerves, if necessary, retrenched, every bleeding artery
is promptly secured, commencing with the main trunk and then tying up successively each
smaller branch until the flow of blood is effectually arrested.

It is seldom that more than from four to six arteries require to be tied, especially when
the operation is performed on account of recent injury. When, on the contrary, a limb

is removed on account of a morbid growth, as, for example, a sarcomatous tumor, elephantiasis, or chronic inflammation, the smaller arteries are often immensely enlarged, and may, therefore, each demand separate attention. A similar arrangement generally exists when the main artery of a limb has been obliterated, whether designedly or acci-

Fig. 221.

Bone Nippers.

dentally, for then all the anastomotic branches carry an unusual amount of blood to atone for the loss sustained by the interruption of the principal channel. Hence we occasionally hear of cases in which as many as twenty, thirty, and even forty ligatures were applied before the hemorrhage could be completely arrested. Such a necessity is always to be regretted on account of its liability to be followed by serious inflammation and suppuration from the irritation of so much foreign material.

Hemorrhage of a troublesome kind often arises when the flaps in an amputation are taken from parts recently in a state of inflammation, as the arteries are then firmly embedded in the tissues by partially organized plasma, and so rendered incapable of retracting and of being drawn forth with the forceps or tenaculum. When this is the case the vessels must be separated with the knife, or controlled by acupressure.

Not a little trouble is often experienced in checking the flow of blood from the veins, especially in amputations of the thigh and leg, performed on account of chronic disease, as old ulcers, long-continued inflammation, and various morbid growths. When this is the case, the bleeding vessels, which are sometimes quite varicose, may either be tied in the same manner as an artery, compressed by means of a long needle, as in ordinary acupressure, or occluded with a very small pair of forceps, as suggested by Mr. G. H. Porter, of Dublin, the instrument being removed at the end of forty-eight hours. Great prejudice exists against ligating veins, but experience has shown that the fears that are entertained upon this subject are, if not entirely ill-founded, greatly exaggerated. The largest veins, as the internal jugular and femoral, have repeatedly been tied with impunity. I have myself never hesitated to adopt this treatment when occasion seemed to demand it; and in no instance, so far as I remember, have any evil consequences ensued. The testimony of other surgeons is equally conclusive upon the subject.

That the fears of exciting dangerous inflammation of the veins by the application of a ligature are utterly groundless, has been conclusively demonstrated by Dr. S. W. Gross, in an elaborate communication in the American Journal of the Medical Sciences for January and April, 1867. Of forty cases of ligation of the internal jugular vein, analyzed by him, death was fairly ascribable to the ligature in only four, all due to secondary hemorrhage, coming on about the time of the separation of the thread. In not a single instance was diffused phlebitis excited. Since the publication of his paper, Dr. Gross has analyzed twenty cases of ligation of the external jugular vein, and fifteen of the axillary vein, which add additional testimony to the safety and efficiency of the ligature, inasmuch as all did well.

The troublesome bleeding which occasionally proceeds from the nutrient artery of the bone is usually easily arrested by plugging the orifice temporarily with a piece of soft wood, or a little tampon of lint attached to a thread. The oozing from the end of the bone sometimes requires the application of a lint compress, but, in general, it speedily stops of its own accord, or under the influence of the contact of cold air, or hot water. The sponge occasionally used in this form of hemorrhage is objectionable, as it is liable to contract firm adhesions, rendering its separation difficult, and endangering the occurrence of osteomyelitis and the rapid healing of the stump.

After-Treatment.—As it respects the permanent dressings after amputation, they should be of the lightest and most simple character. In the larger operations they should not, as a rule, be applied under four or five hours, or until the wound is well glazed with lymph, and all danger of hemorrhage past. It is difficult to conceive of anything more awkward for the surgeon, or more disagreeable to the patient, than the necessity of undoing the dressings, some hours after the removal of a limb, for the purpose of searching for bleeding vessels. Such a procedure is sure to cause alarm and suffering; and, although it is

always, in ordinary cases, desirable to complete the dressings as early as possible, yet after a large amputation, involving vast and numerous muscles liable to conceal arteries of considerable size, I regard it as a matter of great consequence not to hazard the necessity of their removal. During the period that intervenes between the operation and the permanent dressings, the limb should be placed in an easy, elevated position, and the flaps should either be loosely approximated with a few adhesive strips, or, what is better, left apart, and covered with light compresses wet with cold water, and frequently irrigated; not changed, unless soaked with blood, as this would only lead to exposure and irritation of the parts.

The rules here laid down are chiefly applicable to amputations in civil practice. In operations of this kind performed on the battle-field no such delay is, of course, admissible.

All bleeding and danger of bleeding having ceased, the flaps are carefully stitched in place, the ligatures are brought out at the nearest points, and the intervals between the sutures are covered with long and rather narrow strips of plaster, to admit of proper drainage. This should be still further favored, when the breach is very large and deep, by the insertion of a slender tent in the lower angle of the wound, and by strict attention to the position of the stump. To a want of these precautions are unquestionably to be ascribed some of the bad effects of these operations, as septicemia, profuse suppuration, and the death of the extremity of the bone. The wound being firmly closed at all points the matter, of which there is nearly always more or less after all large amputations, accumulates in the depths of the stump, around the bone, and among the muscles, thus causing necrosis of the former, and affording the veins and lymphatics of the latter an opportunity of conveying the fluid into the system, and thereby inducing blood-poisoning. All this risk may be effectually prevented by adopting the plan here suggested of keeping a long, slender, and well-oiled tent in the lower part of the wound for the first thirty-six or forty-eight hours; at the end of this time it may be carefully removed, and any pus that may be present gently pressed out. A gum-elastic tube may now, if necessary, take the place of the tent, with a view to more ready and steady drainage, or, if the suppurative crisis is passed, the foreign body may be dispensed with, and the case managed in the ordinary way.

When numerous ligatures are required to arrest the bleeding, as in some of the larger amputations, performed on account of chronic disease or morbid growths, the best plan is to bring out their extremities at the nearest points of the flaps, instead of at the edges of the wound, by means of a large, long, slender needle. Such a procedure will not only abridge suffering, but greatly promote the chances of primary union. Chromicized catgut ligatures, to which I have recently resorted in all my amputations, are preferable to the ordinary ligature, and will, doubtless, come into general use.

The adhesive strips must, if possible, extend four or five inches beyond the upper extremity of each flap, especially in the larger amputations, so as to prevent the retraction of the integument, and also for the purpose of quieting the muscles and bringing them well forward over the bone. I have been in the habit for many years of beginning the application of the roller at the part of the limb nearest to the trunk, carrying it firmly and equably downward to the very verge of the stump, which is then enveloped by a few crucial turns of the bandage, to give it greater support. No other dressing is necessary. The limb is placed in an easy and slightly elevated position, upon a pillow or splint covered with oil-cloth, and kept constantly wet with cold water, applied by means of a light, porous towel, renewed whenever it becomes in the slightest degree bloody or offensive. If suppuration be threatened, or the cold is disagreeable and chilling in its effects, the most eligible substitute will be an emollient cataplasm or warm water-dressing medicated with lead-water and laudanum. The stump is of course carefully protected from the contact of the bedclothes. As soon as the operation is over, a full anodyne is ordered, for the twofold purpose of relieving pain and preventing spasm, the dose being afterwards repeated from time to time as circumstances may seem to demand. The diet should be light, but rather nourishing than otherwise; and, with the exception of a mild aperient on the second day, no medicine whatever should be given unless it is absolutely necessary on account of the violence of the traumatic fever, or the danger of exhaustion from shock and hemorrhage. When the system is much depressed at the time of the operation, the patient should at once be put upon the use of quinine and iron along with a generous diet, aided, perhaps, by milk punch. From what I have seen of such cases, I am satisfied that the worst possible plan that can be pursued is starvation, as this not only weakens the system still further, but tends powerfully to the production of pyemia, erysipelas, and typhoid fever.

The dressings may require removal within twenty-four, thirty-six, or forty-eight hours

after the operation, or not under three or four days, according to the condition of the parts. When the adhesive action is progressing favorably, the less interference there is the better, any discharge that may collect on the surface of the stump being soaked up with a soft sponge. If considerable swelling and pain take place, or profuse suppuration set in, the change cannot be effected too soon or too frequently, the limb being well supported while this is being done by an assistant, at the same time that all pressure and unnecessary manipulation are avoided. Any tendency to bagging is to be counteracted by the judicious application of adhesive strips and the bandage, aided by declivity of the stump, so as to favor drainage, now of vital importance both to the part and system. Permanganate of potassium or chlorinate of sodium is freely used as a stimulant and a deodorizer. The sutures should not be cut out too soon; as long as they are affording support they should be permitted to remain.

The antiseptic and cotton-wool dressings, to which reference is made on page 346, are much employed in this class of cases; but as I do not believe that they possess any advantages over the simple treatment which I have just described, I never resort to them.

A mode of treatment, known as pneumatic aspiration, intended to exclude the air from the stump, has been extensively practised in some of the Parisian hospitals, especially in the wards of the Hôtel-Dieu, by Maisonneuve, its inventor. It simply consists in surrounding the stump with a closely-fitting hood of vulcanized India-rubber, to the centre of the free extremity of which is attached a tube, of similar material, from two to three feet in length, the opposite end of which is fitted, by means of a metallic canula, in a rubber plug secured in a gallon glass jar. "A second metallic tube pierces the India-rubber plug, and is connected with a vulcanized tube, of convenient length, attached to a brass exhausting pump. A few strokes from the piston morning and evening suffice to draw the discharges from the stump into the jar, where, in the absence of air, they accumulate without danger of decomposition; while the healing of the wound is facilitated by the accurate and immovable adaptation of its surfaces, and the exclusion of air." It is proper to add that the edges of the wound are held together simply with adhesive plaster, unaided by sutures.

Of the efficacy of this mode of treatment facts are still wanting to enable us to form an accurate opinion. Mr. Gamgee, of Birmingham, who has called the special attention of English surgeons to it, speaks of it in very flattering terms, and in the hands of its inventor it seems to have already achieved great success.

The treatment of amputation by the "open method," as it is termed, orginated by Burow, of Germany, and introduced into this country nearly simultaneously by Dr. J. E. Link, of Indiana, and Dr. James R. Wood, of New York, deserves more consideration than has hitherto been accorded to it. My conviction is that, as a rule, it is preferable to every other plan that has ever been devised; more rational, more safe, and more free from the risk of complications and bad consequences. Dr. Link, in 1875, reported 190 cases of amputations treated in this manner, 150 in military, and 40 in civil, practice, with results eminently gratifying; and Dr. Wood, who introduced the method many years ago, at Bellevue Hospital, has achieved with it the most remarkable success. In nearly one hundred operations of this kind performed upon the upper and lower extremities, including the wrist, elbow, shoulder, ankle, and knee-joints, there was not one death which, as he informs me, could justly be ascribed to blood-poisoning, or to the exposure of the stump to the air, although, as a rule, his patients were in an indifferent physical condition, and often in bad hygienic surroundings. He lays great stress upon the manner in which the amputation is performed; his flaps, which are either lateral or antero-posterior, are entirely cutaneous, every particle of muscular substance being excluded, and everything is done with reference to thorough drainage. The "open method" has found warm advocates in Professor Humphry, of Cambridge, and in Mr. Teale, of Leads; and it may safely be predicted that the day is not distant when it will be generally adopted.

In this mode of dressing, the flaps are left completely open, sutures, adhesive strips, and bandages being dispensed with during the first week. The wound is washed immediately after the operation with a moderately strong solution of carbolic acid, and then filled with balsam of Peru, the drainage, as practised by Dr. Wood, being completed by interposing between the flaps a pledget of oakum soaked in the balsam. The stump is left in this condition during the first twenty-four hours, unless it become hot or painful from overaction, when it must be removed at once. After this period the wound is washed twice daily with weak carbolized water by means of a douche or syringe, and treated with balsam and oakum as in the first instance. When the suppuration has nearly ceased, as it usually does by the end of the sixth or eighth day, the flaps are moulded into shape, and gradually

approximated with adhesive plaster. As this mode of treatment is attended with an un-
usual shrinkage, the flaps must be made proportionally large. The "open method," while
admitting of free drainage, leaves an excellent stump, and is not liable to be followed, as the
ordinary close dressing, by erysipelas, abscesses, pyemia, septicemia, or suppurative fever.

The ligatures should be removed as fast as they are detached, with as little injury as
possible to the vessels and other structures. Their unnecessary retention is a great evil.
That around the main artery will generally come away last, and special care should be
taken not to make any undue traction upon it, as its premature separation might be fol-
lowed by serious, if not fatal, bleeding.

Secondary hemorrhage occurring after amputation must be treated upon general prin-
ciples; by the ligature, if this be practicable, at the stump; by styptics, as the subsulphate
of iron; or by the compress, applied either directly to the orifice of the bleeding vessel,
the wound having previously been thoroughly dried, or indirectly over the course of the
affected vessel. The latter expedient is often successful after amputation even of the
larger limbs. When everything else fails, the only resource is ligation of the main artery
of the extremity some distance from the seat of the operation.

After the wound has healed, the stump should be protected for some time with a piece
of soft flannel, to prevent the ill effects that might otherwise arise from atmospheric vicis-
situdes; and all pressure upon its surface should be carefully avoided until the parts have
regained their natural sensibility.

Synchronous Amputations.—In cases of accident, as well as in certain diseases, but
especially in the former, it occasionally become necessary to amputate two limbs simulta-
neously, or in immediate succession, the circumstances which call for the removal of the
one demanding the separation of the other. This constitutes what is termed the synchro-
nous double operation. It is founded upon the assumption that recovery is more rapid
when two limbs are cut off simultaneously than at two separate and distinct periods; that
the loss of blood will be comparatively little more from two amputations thus performed
than from one alone; that there will be in the aggregate, much less pain, shock, and
inconvenience; and, lastly, that the patient will thus escape the harassing anxiety of mind
growing out of the knowledge that he will be obliged to submit to another operation.
Synchronous double amputation has occasionally been performed in various parts of this
country and Europe; but, so far as my information extends, it was first adopted, as a rule
of practice, by the surgeons of the Hôtel-Dieu, at Quebec, the first case having occurred,
many years ago, in the hands of Dr. Morris, of that city. Within the last twenty-five
years the operation has also been performed by Dr. Carnochan, Dr. S. W. Gross, Robert
H. Seiler, Paul F. Eve, Amerman, and a number of other surgeons. In 1847, Dr. John
G. Koehler, of Schuylkill Haven, Pennsylvania, removed simultaneously, on account of a
railway injury, both legs and one arm from a lad, thirteen years of age, recovery taking
place without the supervention of any serious symptoms. The limbs were frightfully
crushed, and the operation was performed within a short time after the accident. The
arm being cut off first, the pulse immediately sank, but under the influence of stimulants
it rose sufficiently in five minutes to justify amputation of both legs below the knee. So
excessive had been the shock of the system that the boy hardly experienced any pain
during the operation. Professor Stone, of New Orleans, had a similar case, equally
successful, in a man, thirty-three years of age, the subject of a railway accident. Dr.
Alfred Müller, of the army, in 1866, amputated both arms on one day, and both legs on
the next, on account of frostbites, the patient making an excellent recovery. Mr. Begg,
of Dundee, Scotland, in 1869, amputated all the extremities in a young woman on account
of embolic gangrene, and she not only recovered but has since been able to walk with the
aid of crutches, and to earn a livelihood by knitting and various other kinds of work.
She feeds and dresses herself, and writes an excellent hand. This case, apart from its
pathological value, as indicating how life may be saved by judicious interference in
embolic gangrene, is of special interest as showing how lost parts may be supplied by
ingenious mechanical contrivances, so as to be of great use to an individual who would
otherwise be wholly helpless. Professor Ashhurst, in 1879, removed successfully, on
account of railway injury, the left leg at its middle and the right lower extremity at the
hip-joint, from a boy thirteen years of age.

The synchronous double operation may be performed by two surgeons, or by one alone,
the latter being perhaps the preferable method. In either event, it is a matter of para-
mount importance to protect the patient from the loss of blood, the slightest effusion of
which might prove prejudicial to his safety. Dr. Carnochan cuts off both limbs before

he ties any vessels, and this is undoubtedly the preferable plan if we can be certain of having perfect control over the hemorrhage, as when proper assistants are at hand, and the removal is effected rapidly by the flap operation. Synchronous amputation of the lower extremities may be performed with very little loss of blood, with the aid of the abdominal tourniquet.

The prognosis of synchronous double amputations is, of course, for obvious reasons, more unfavorable in the lower extremities than in the upper. Experience shows that the operation, when performed for gunshot injuries through both legs, knees, and thighs, is nearly always fatal. Both feet, hands, arms, and forearms, on the contrary, may generally be removed with comparative impunity.

Reamputations.—Such operations may become necessary on account of the bad shape of the stump, as when it is too square or too conical, great retraction of the skin and muscles leading to protrusion of the bone, extensive caries of necrosis, ulceration of the soft parts, and hypertrophy of the nerves, attended with neuralgia and exquisite morbid sensibility. The suffering that may be caused by some of these affections may not only greatly interfere with progression and the use of an artificial limb, but seriously impair the general health and render life perfectly miserable. I have seen cases where the extremity of the stump was so irritable as to be intolerant of the slightest touch, the patient screaming and wincing as if he had been electrified.

A second amputation should be performed upon the same principles as a first one. If the general health is much deranged, the knife should be withheld until it has been rectified, otherwise serious, if not fatal, consequences may ensue. Instead of amputation, resection may sometimes be advantageously performed, the offending parts being removed either with the scalpel, or the scalpel and pliers. Hemorrhage is carefully guarded against, as the slightest loss of blood may prove highly prejudicial.

The question has of late years been much agitated, whether, when the bone of a stump is extensively diseased, it would not be better to exarticulate the limb than to reamputate in its continuity? Valette and Roux, two eminent French surgeons, of large experience as military practitioners, have expressed themselves warmly in favor of the former procedure, on the ground that there is always great danger, when a bone has been affected with osteomyelitis, of a persistence of the morbid action, despite every possible precaution that may be used in the removal of the limb in its continuity. The cases under the care of Valette were, it would seem, principally of an acute character, while in those of Roux the disease had attained its chronic stage. The practice advocated by these surgeons cannot, in my judgment, be too strongly condemned, as it is alike harsh and hazardous. In acute myelitis, the proper course, as a general rule, is, to wait until, under appropriate local and constitutional measures, the disease is effectually arrested, when the mere extraction of the sequester will commonly suffice to effect a cure. If this do not answer the purpose, the bone may be safely excised, or the limb may be reamputated in its continuity, an operation especially indicated when, superadded to the disease of the bone, there is serious lesion of the soft parts, or a very defective condition of the stump from loss of substance. If it be said that the patient cannot, from the drain and irritation consequent upon such an affection, successfully struggle through the period necessary for the arrest of the morbid action, it may be replied that such an occurrence, although possible, is not probable, and that it must, therefore, be viewed as an exceptional circumstance.

As it respects the chronic form of osteomyelitis, I am satisfied, from personal experience, that exarticulation, so ably advocated by Roux, can only be required in exceptional cases. Ordinarily, it will be quite sufficient to remove the sequester, to excise the bone, especially if it be carious and disintegrated, or to reamputate in the continuity of the limb. With this statement the results of the observations of our army surgeons fully coincide. Dr. Richard J. Levis, during his connection with the large government hospital of this city for the treatment of diseased stumps, was not obliged to exarticulate in a single instance. He always accomplished his object by the adoption of some one of the operations here specified.

I am aware, as is every surgeon of experience, that, in chronic osteomyelitis, the part and system become inured to suffering, and, consequently, more tolerant of interference; but this, surely, is no valid reason for substituting so hazardous an operation as exarticulation for one so simple as the extraction of a sequester, the excision of a carious bone, or even the amputation of a stump in the continuity of a limb.

It is not often that a limb is obliged to be reamputated more than once on account of a bad stump. The existence of neuralgia requires such interference, perhaps, more

frequently than any other affection. At all events, it is in this class of cases that the operation has most commonly been performed. Instances have been reported in which one part of an extremity after an other has been sacrificed for the relief of this disease, and yet no ulterior benefit accrued even after amputation at the shoulder or hip-joint.

Spontaneous Amputations.—Under this head may be briefly described those amputations which occasionally occur during utero-gestation, in consequence of the constriction of a limb by a cord or band of plastic matter. Such accidents, which are, surgically considered, of comparatively little interest, are usually designated by the term "spontaneous," and are liable to take place in the upper as well as in the lower extremities, in the larger as well as in the smaller limbs. The division is sometimes complete, at other times partial.

The cause of this occurrence was for a long time a mystery. The prevalent opinion, up to a comparatively recent period, was that it was due to gangrene developed during fœtal life by some agent, the precise nature of which no one could explain. Unfortunately, however, for this view of the case, no evidence was ever discovered, either in the amputated limb or in the stump, of the existence of such a condition, and, consequently, the notion was at length abandoned. It remained for Professor Montgomery to solve the enigma. In a paper published in the Dublin Journal of Medical Science for May, 1832, he distinctly asserted that the agency by which the lesion is produced is a cord or band of false membrane, thrown accidentally around a limb, acting on the principle of a string, drawn more and more tightly by its own contraction, until, if the pressure be continued, complete severance of the tissues, hard as well as soft, is effected. That this explanation is correct is, I think, unquestionable. The fact that lymph is liable to be poured out by the surface of the child, by the placenta, and by the umbilical cord, during pregnancy, is well established, and every pathological anatomist knows how prone such matter is, when it has become organized, to contract and shrink. This tendency to contract and shrink steadily increases with the age of this substance, and, hence, it is easy to conceive how a cord or band of membrane might, if drawn firmly around an arm or leg, eventually lead to its separation. Zagorsky has published a drawing of a case which affords an excellent illustration of partial and complete amputation of the leg by a process of this kind. The foot of the severed limb is suspended, as it were, from the centre of the fibrous cord. The fœtus, which had attained the fifth month, was greatly deformed in the head and hands, especially the left. In a remarkable instance described in the London Medical Times and Gazette for 1853, intrauterine amputation took place in all the limbs. The child was born alive, and was in all other respects well formed.

The stump after such an occurrence is not always well shaped, and may, therefore, if the child survive its birth, require retrenchment or improvement. In general, however, it is perfectly cicatrized, and sufficiently seemly. Now and then inconvenience is experienced by the protrusion of a piece of bone, the removal of which is followed by a speedy cure.

SECT. V.—AFFECTIONS OF THE STUMP.

These affections are either of a primary or consecutive character, and both may be purely of a local, or of a local and constitutional origin. The primary consist of hemorrhage, spasm of the muscles, excessive pain, undue inflammation, osteomyelitis, and inordinate retraction of the soft parts, thereby permitting exposure of the bone. Among the secondary effects may be mentioned necrosis and exfoliation of the bone, degeneration of the nerves and neuralgic pain, aneurismal enlargement of the vessels, and contraction of the tendons in the neighborhood of the stump, by which the latter is drawn out of its proper position, and so made a source of inconvenience and discomfort.

1. PRIMARY AFFECTIONS.

a. Hemorrhage may come on soon after the dressing of the stump, or not until some time has elapsed; perhaps not for several days. It is usually occasioned by the want of a sufficient number of ligatures, in consequence of the retraction of some of the smaller arteries, thereby escaping the surgeon's attention while he is looking out for the principal and more accessible branches; or it may be that the vessel has been cut obliquely, and that it has not been tied high enough up; or that the arterial tunics are so much diseased as to give way under the pressure of the cord before the formation of an adequate internal clot, as when the bleeding supervenes several days after the operation; or, finally, that the vessels are embedded in inflamed tissues, and, consequently, incapable of retraction.

However induced, or whatever may be the circumstances which give rise to the hemorrhage, the proper remedy consists in exposing the open artery, and securing it with a ligature, either by separating the flaps, or, if adhesion is already far advanced, by dilating the canal along which the blood flows over a grooved director. The main artery of the limb is not tied unless it be found impossible, on account of disease, or some other cause, to effect ligation at the stump.

Sometimes the hemorrhage is purely venous, the blood flowing away lazily in a dark purple stream, without any jet, and then it will generally be found to depend upon the want of accurate coaptation of the flaps, or some defective application in the bandage, making either too little or too much pressure ; in the former case keeping the vessels open and gaping, in the latter interfering with the passage of their contents. Occasionally the blood oozes out at different points, as water oozes out of a sponge, and this may take place either from the soft parts, or from the Haversian canals of the bones, or from the medullary membrane and the marrow. Arrest of the bleeding is usually effected simply by compression of the stump, the compress and roller being made to bear steadily against the offending vessels, aided by elevation and cold applications; when this fails, the ligature may be required. When the blood proceeds from the Haversian canals, it will generally be necessary to undo the flaps, and apply a compress directly to the surface of the bone, the wound being kept open until the flow is arrested. Caustic applications must not be used, as they might cause necrosis.

β. *Spasm* of the muscles, which is frequently a source of deep distress, and which presents itself in the form of jerks or twitchings, usually sets in within a few hours after the operation, and is generally most severe in persons of a nervous, irritable temperament. No patient, however, is ever entirely exempt from it after amputation, and it is always sure to be materially aggravated on the occurrence of inflammation. In regard to treatment, much is to be done in the way of prophylaxis ; by the judicious use of the roller to give equable support to the muscles of the stump, by elevation of the part to favor venous return, and also by the early exhibition of a full anodyne. The use of morphia, or of morphia and antimony, along with warm fomentations, will be required if the spasm is at all severe, as when no such precautionary measures have been adopted. In most cases prompt relief may be afforded by the subcutaneous injection of morphia.

γ. The degree and continuance of the *pain* which follows an amputation will be influenced very materially by the character of the case, the size of the limb, the presence or absence of complications, and, above all, by the temperament of the patient. Coming on usually as the system emerges from the influence of the anæsthetic, it is sometimes remarkably slight, while at other times it is so severe as to require large quantities of anodyne medicines for its relief. When the pain is associated with spasmodic twitching of the stump, as it generally is during the first twenty-four hours, it must be promptly met with anodynes, or anodynes and antimony. In order to render these two phenomena as light as possible, I have long been in the habit of administering a full opiate about two hours before the operation, and have never been disappointed in my expectations.

δ. The *inflammation* consequent upon an operation of this kind may be either of the ordinary character, or it may be erysipelatous, the determining circumstances not being always appreciable. In general, however, the danger of erysipelatous action will be considerable when there has been severe shock or excessive loss of blood, conjoined with previous bad health or habits of intemperance. It usually makes its appearance within the first forty-eight hours, and is characterized by the ordinary phenomena, such as a red, dusky state of the skin, more or less throbbing, a sense of tension, and burning, smarting pain, with marked disorder of the general system. Whatever may be the degree or character of the inflammation, it is always hostile to the adhesive process ; some parts may, it is true, unite in this way, but suppuration will be almost sure to follow, so as to lead to the necessity of healing the greater portion of the wound by granulation. In persons of a very dilapidated constitution the inflammation may pass into gangrene. I have found this termination most commonly in patients of a scrofulous habit of body and in those whose system has been contaminated by syphilis.

When the suppuration takes place, as it will be very apt to do when there is much inflammation, the matter is often widely diffused, burrowing extensively along the intermuscular spaces to a great distance up the stump. This is particularly liable to happen in amputations in the lower part of the forearm and leg, the hand, and tarsus, owing to the numerous synovial sheaths in those situations readily permitting the entrance of the pus.

Gangrene is often quite common after amputations in crowded military hospitals and barracks, and on board transports, from the vitiated condition of the atmosphere, and the generation of noxious emanations, which, rapidly depressing the vital powers, induce a low form of fever, and cause every wound, sore, or ulcer, however insignificant, to assume an unhealthy, sloughing appearance.

The treatment of this disease must be conducted upon general antiphlogistic principles. Special attention must be paid to the state of the system, and with this view it will generally be necessary to employ a mildly stimulating course, consisting of quinine and milk punch, with blue mass and ipecacuanha to evacuate the bowels and correct the secretions. Morphia is given in liberal doses to allay pain and procure sleep. The most suitable local remedies are dilute tincture of iodine, and fomentations or cataplasms medicated with solutions of acetate of lead and opium. Leeches generally prove prejudicial. Sometimes the disease is promptly arrested by the application of a large blister. Inordinate tension and confined fluids are relieved by puncture and incision. Abscesses are opened and sinuses traced out in the usual manner, infiltration of pus being always zealously guarded against. Counteropenings are made wherever they are likely to be useful, as affording a more ready exit to the pus. If mortification is threatened, the parts are freely touched with nitrate of silver, sulphate of copper, or dilute acid nitrate of mercury, and enveloped in a fermenting poultice. The chlorides are used for allaying fetor, and the syringe for washing away secretions from beneath the flaps.

ε. Bad effects occasionally follow amputation as a result of *osteomyelitis*. In the Crimean war this affection was of such frequent occurrence after gunshot injuries that the question was at one time seriously debated by a number of surgeons whether it would not be best to abandon amputation altogether in the continuity of the larger bones, and resort to disarticulation as a substitute. The disease is also sufficiently common in hospital and private practice, especially in railway and other severe accidents, attended with violent concussion of the osseous tissue. The probability is that it is occasionally caused by injury inflicted in sawing the bone. However induced, it generally sets in within a short period after the operation, so that by the time the dressings are removed, as they usually are on the third, fourth, or fifth day, it is found to have already made considerable progress, the marrow being of a brownish, blackish, or greenish appearance, of a soft, putrilaginous consistence, excessively fetid, and partially detached from the bone, which is itself either dead, or in a dying state, and more or less denuded of periosteum. The disease is generally attended with considerable pain, although in some of the cases that I have seen there was almost an entire absence of local suffering. It is not unfrequently coincident with pyemia and erysipelas. Hence the prognosis is often exceedingly unfavorable.

The treatment of osteomyelitis must be antiphlogistic, modified by the peculiarity of the constitutional symptoms. Great attention must be paid to cleanliness; the dressings must be frequently changed, and free use made of weak solutions of chloralum, permanganate of potassium, or thymol. The judicious application of nitrate of silver to the affected structures might possibly assist in circumscribing and ultimately arresting the morbid action. If the bone die, no attempt should be made to remove it until the part and system have sufficiently recovered from the effects of the disease to bear the shock of the operation.

ζ. Finally, amputation is occasionally followed by inordinate *retraction* of the muscles, so as to uncover the bone, and, perhaps, lead to the necessity of its removal. The acci-

Fig. 222.
Thigh Stump, with Splint for Extension.

dent is most liable to happen after amputation of the thigh, in consequence of the action of the numerous, large, and strong muscles in that situation, and cannot always be pre-

vented even when more than ordinary care is taken in forming the stump.   The occurrence is always to be deprecated, inasmuch as it not only interferes with the union of the flaps, but is very apt to cause the death of the bone.   The remedy consists in bandaging the limb firmly from above downwards, preceded by the application of long adhesive strips, and in placing the parts in the best condition for relaxing the affected muscles. Professor Warren, formerly of Baltimore, has suggested, in cases of this kind, the employment of extension by means of adhesive strips, weight and pulley, as seen in fig. 222, from Bryant, upon the same principle as in the treatment of fractures, and has published the results of some cases illustrative of the beneficial effects of his method.   When these means are unavailing, we may, provided the bone remains sound, divide some of the muscles of the stump subcutaneously, and then draw them forward, either with or without incision of the integument, as the case may seem to demand.   If the bone, however, is diseased, the best plan will be to saw it off higher up ; but such an operation is often more hazardous than the original one, and should, therefore, always, if possible, be avoided.

2. SECONDARY AFFECTIONS.

The most common, as well as the most serious, secondary effects of amputation are, as was previously stated, hemorrhage, necrosis, caries, neuralgia, synovial bursæ, varicose enlargement of the arteries, and permanent shortening of the tendons in the vicinity of the stump.

a. Secondary *hemorrhage* is by no means uncommon after amputations, especially in persons exhausted by intemperance, loss of blood, and other debilitating influences, and usually depends either upon the premature detachment of the ligature from ulceration of the arteries, or upon the supervention of gangrene, by which the structures of the stump are softened and disorganized before the vessels are sufficiently occluded by clots and plastic matter.   The bleeding may be sudden and copious, or gradual and slight, though ultimately, if not checked, not the less surely injurious, or even fatal.   It seldom occurs before the tenth or twelfth day, and frequently not until after the third week.   The blood may ooze out at many points, or, if not, in a full stream, either arterial or venous ; more commonly the former.   In the more ordinary cases, the flow may occasionally be promptly arrested by systematic compression, applied directly over the course of the affected artery, immediately above the bleeding orifice ; or, instead of this, the vessel may be included along with some of the surrounding tissues in a ligature.   Now and then the object may be attained by means of an acupressure needle.   When all these attempts fail, the only resource is to cut down upon the main trunk of the artery, some distance above the stump, and to secure it with a ligature, as in the operation for aneurism.

A troublesome form of hemorrhage sometimes accompanies necrosis of the stump, the blood oozing away at each dressing from the gap between the dead and living structures, much to the detriment of the patient and the annoyance of the surgeon.   It evidently depends upon the inability of the vessels in the indurated and diseased parts immediately around the dead bone to retract and occlude their orifices, and generally promptly ceases upon the removal of the sequester, the exciting cause of the hemorrhage.

Fig. 223.

β. Disease of the bone, eventuating in *necrosis*, may be induced in various ways : in general, it is caused by injury inflicted upon it during the operation, consisting either in the laceration and separation of the periosteum, in the excessive jarring of its substance, or in the violence inflicted upon its nutrient artery, thereby cutting off its wonted supply of blood.   Uncovering of the bone, in consequence of too great a brevity of flap, and the accumulation around its extremity of pus, are also very apt to produce it.   Sometimes it perishes from the intensity of the inflammatory action.   The loss of vitality is indicated by the peculiar whitish, greenish, or pale yellowish aspect of the bone, the absence of bloody points upon its surface, and a characteristic hollow noise when struck with the handle of the knife.   The marrow and its envelop generally retain their vitality for a short time after the osseous tissue has died, an event most likely to happen when the bone perishes only in a part of its circumference.   Necrosis, as a result of amputation, is more liable to occur in the thigh-bone than in any other piece of the skeleton,

Necrosis of the Bone after Amputation.

depending probably upon some peculiarity of its organization.   The tibia is also occasionally affected, and a similar occurrence is sometimes met with in the humerus.   The dead bone may come off in the form, first, of an exfoliation, consisting merely of a part

of its outer compact substance; or, secondly, as an osseous ring, with long, narrow, sharp spicules; or, finally, as a complete cylinder or tube, as when it involves several inches of the entire circumference of the bone. The more common appearances of the necrosed bone are exhibited in fig. 223.

The management of these cases must be left very much to the operation of time, especially when the bone has perished high up, and when, in order to reach it, extensive dissection would be required. If, on the other hand, the necrosis is very limited, an attempt may be made to get rid of it with the saw, cutting forceps, trephine, or burr of the surgical engine. Too much caution, however, cannot be used in such an operation, trifling as it appears to be. I have seen death produced by it in two cases, and similar instances have been witnessed by others. It would seem, when a bone is thus affected, as if the system were more than usually intolerant of instrumental interference and loss of blood; the parts are generally excessively irritable, and the constitution rarely fails to sympathize with them in the most lively manner. Besides, the operation is necessarily attended with some degree of hemorrhage, and I am not certain that a patient may not be destroyed in this way alone, especially if he is very feeble and irritable at the time.

Instances occur in which the sequester is firmly, and even obstinately, imprisoned by the remains of the living bone; or, more properly speaking, by the new matter that is thrown out upon its surface, thus occasioning great difficulty in regard to its removal. In a case kindly communicated to me by Professor Markoe, of New York, the sequester, consisting of an inner shell of the femur, was retained for many months by a spur of new osseous substance extending through an opening in its sides, in such a manner as to nail the dead and living parts together, but at the same time allowing the former to be moved freely backwards and forwards upon the latter. It was not until after several attempts had been made at extraction, attended with much pain and constitutional suffering, that riddance was finally effected by means of the chisel and forceps.

γ. *Caries* of the bone, as a consequence of amputation, is by no means uncommon. I have also seen cases where it was obviously due to injury inflicted previously to the operation, as when a bone has been severely jarred by a blow, fall, or a partially spent bullet. In this condition it is not unusual to find the caries conjoined with necrosis, one part of the bone being in a state of ulceration, while another is completely deprived of vitality. When the disease is of long continuance, the areolar and compact tissues have an inflamed, discolored appearance, and their consistence is so much diminished that they may be cut with the knife or crushed with the finger; the periosteum is opaque, thickened, and easily pealed off; and the medullary canal is either completely hollowed out, or occupied by a softened, reddish, pulpy substance, without any trace of marrow and endosteum.

No stump can, of course, be healthy under such a state of disease. The bone keeps up constant irritation; abscess after abscess forms; and the soft parts, incessantly inflamed and swollen, are tender, painful, and intolerant of pressure. The proper remedy is excision of the affected bone, or reamputation, according to the extent of the disease.

δ. A stump is sometimes rendered exceedingly painful and uncomfortable by the development of an *exostosis* upon the extremity of the bone. The new growth generally presents itself in the form of a stalactite, or of an elongated, spur-like projection, narrow, cylindrical, straight, or crooked, from an inch to an inch and a half in length, and of variable thickness. The proper remedy is excision.

ε. Another disagreeable, frequently, indeed, a most distressing effect of this operation, is *neuralgia*, coming on at a variable period after its performance, and often continuing, despite the most judicious and persevering efforts at relief, to molest the patient during the remainder of his life. Supervening generally without any assignable cause, it is most common in nervous, irritable persons, subject to the disease in other parts of the body. Women are more prone to it than men, and in them the attack frequently coincides with the eruption of the menses. Sometimes the disease is periodical, especially in residents in malarial regions, the paroxysms coming and going very much as in intermittent fever. Most commonly, however, the pain is irregular, one portion of the day being as liable to it as another. It is generally of a darting, shooting nature, or dull, heavy, and aching, and is invariably aggravated by damp states of the atmosphere, fatigue, and disorder of the digestive apparatus.

In the more violent forms of this affection the immediate cause of the suffering is a bulbous enlargement of the nerves ramifying through the stump, as in fig. 224. This degeneration takes place, to a greater or less extent, after nearly every amputation, and is, therefore, to be considered as a disease only when it exists in excess. Under such circumstances the tumor, which sometimes attains the size of a hickory-nut, or even of a

pullet's egg, is of a firm, dense consistence, and is composed of a strong fibrous stroma, inlaid with hypertropied and curiously interlaced nervous trunks and filaments. It is, in fact, a true neuroma. The accompanying pain is exquisite, and the part is so sensitive as to be intolerant of the slightest touch ; the general health is much affected, and the patient is remarkably susceptible of atmospheric vicissitudes, every change in the weather from warm to cold and dry to wet being followed by an increase of suffering. The malady is of a much more serious character than the other, and requires proportionately stronger measures. In general, nothing short of removal will avail ; by excision, if the tumor be single and easily accessible, by amputation, if it be multiple and deep-seated. The subcutaneous division of the affected nerves seldom affords even temporary relief, and stretching of the principal nerves of the stump is generally equally futile.

Fig. 224.

Neuromas of a Stump, after Amputation of the Arm A large mass at *a* ; opposite *b* the tumors are more defined.

For the milder varieties of neuralgia the ordinary remedies sometimes suffice, as in neuralgia in other parts of the body, especially quinine ; or, if the patient is anemic, quinine and iron, combined, in either case, with strychnia and arsenious acid, belladonna, stramonium, or aconite ; the effects of the articles being studiously watched, lest an overdose be given, and life placed in jeopardy. Sometimes marked benefit accrues from the exhibition of colchicum and morphia, administered in full doses at bedtime, as one drachm of the wine to half a grain of the salt. These medicines are particularly valuable in subjects with a rheumatic state of the system. Locally, iodine, blisters, issues, and other counterirritants are used, along with anodyne embrocations. Hypodermic injections of atropia and morphia are occasionally serviceable. The stump is well protected from cold, friction, and pressure.

ζ. A remarkable *trembling*—perhaps it might be called a spasm of chorea—of the stump is occasionally met with. I have seen only two cases of this occurrence, both the result of gunshot injury. The affection, in each instance, supervened several months after the amputation, and closely resembled what is called shaking palsy. The muscles were in constant motion except during sleep, when they were perfectly quiescent ; and the stumps were exceedingly susceptible to cold. The general health was good. No mode of treatment that could be devised exercised the slightest influence upon the disease. In one of the cases, the whole of the cicatrice had been cut away without any visible benefit.

η. A *burse* sometimes forms upon the stump, generally immediately over the end of the bone, in consequence of the long-continued pressure of an ill-constructed and ill-adapted artificial leg. The tumor, in time, becomes exquisitely tender and painful, compelling the patient to seek relief. The seat and character of the disease are usually pointed out by the discoloration and swelling of the part, which often fluctuates on pressure. The history of the case, aided by the exploring needle, will readily serve to distinguish it from abscess, the only lesion with which it is likely to be confounded. The proper remedy is excision in the severer grades of the affection, and in the milder a more careful adaptation of the artificial to the natural limb.

θ. Of *fibroid degeneration* of the tissues of the stump a number of cases have come under my observation since the late war, principally in soldiers who had undergone the circular operation with inadequate covering of the bone. In some instances, however, I have also noticed it where there was no such deficiency, from the long-continued pressure of an artificial limb, provoking and keeping up inflammatory irritation. The skin, in these cases, is unusually red, indurated, puckered, tender, exquisitely sensitive, and, here and there, perhaps, even ulcerated. The parts in front of the bones, immediately beneath the skin, are of a dense fibroid consistence, creaking under the knife, of a whitish or grayish color, and composed of a striated matter, interspersed with cells containing nuclei and nucleoli. The only available remedy is excision, conjoined, if there be a deficiency of covering, with removal of a portion of bone. Occasionally reamputation is required.

ι. *Fatty degeneration* of the muscles is always present in old stumps, existing, in greater or less degree, either by itself, or, as is more generally the case, in union with the fibroid transformation. The oily matter gives the altered muscles a peculiar yellowish

appearance, and causes by its pressure more or less atrophy of the fibres, without materially diminishing the size of the stump.

x. *Fracture* of the bone in the stump of an amputated limb is a very uncommon occurrence, and presents nothing peculiar either as it respects its symptoms, its union, or mode of treatment.

λ. Varicose enlargement of the *arteries* of the stump is extremely rare, only a few instances of it being upon record. Unless the disease is unusually extensive, which, however, it is not likely to be, nothing need be done for its relief, as it does not generally act even as an inconvenience.

In a case of this kind, under my care in 1870, in a colored man, twenty-four years of age, the enlargement began nearly six years previously in consequence of amputation of the lower third of the thigh performed on account of a gunshot injury of the knee. The stump was exceedingly conical, and a source of so much suffering as to render it almost impossible to wear an artificial limb beyond a few hours at a time. The femoral and saphenous veins were excessively enlarged and varicose, especially towards the lower part of the stump, where they formed a mass fully the size of an ordinary fist, throbbing and pulsating violently, and emitting the peculiar whirring sound so characteristic of aneurismal varix. As the pulsation could readily be controlled by pressure upon the femoral artery, I cut down upon that vessel at Porter's space, a few lines below Poupart's ligament, and applied a temporary ligature, hoping to effect occlusion: owing, however, to the diseased condition of the artery, and probably also of the blood, ulceration took place at the site of the ligature, followed, on the sixth day, by copious and exhausting hemorrhage, terminating fatally three days afterwards.

Mr. Cadge, of Norwich, has given the particulars of a remarkable case of aneurismal varix found in a stump, after amputation of the ankle-joint. The tumor, situated just above the internal malleolus, immediately beneath the skin, was elastic, pulsatile, two inches in length, and the seat of a peculiar thrill, so characteristic of this class of affections. Compression of the posterior tibial artery readily arrested its pulsation. The annexed sketch, fig. 225, from Erichsen, affords a good illustration of this extremely rare occurrence.

Fig. 225.

Aneurismal Varix in a Stump.

A case of aneurism of the brachial artery formed after amputation of the lower portion of the arm, from injury inflicted by the knife during the operation, has been reported by G. W. Smith, of Plainfield, Pennsylvania. The tumor, upwards of six lines in diameter, was situated about two inches and a half above the point of ligation of the artery, and consisted exclusively of the internal and middle tunics, the outer one encircling it in the form of a well-defined ring. As the stump was not sound in other respects, reamputation was performed. In an instance related by Warner in his "Cases of Surgery," an aneurism formed three times on this vessel after amputation of the arm. For the cure of two of the tumors the artery was tied immediately above the seat of the disease; but for the last, he applied his ligature high up near the axilla, on the principle of the Hunterian operation, and there was no further trouble. In a case reported by Delacour an aneurism formed on the anterior tibial artery after amputation for a compound fracture of the leg; repeated hemorrhages occurred, and life was saved only by ligation of the femoral artery. In all the cases an unsound condition of the coats of the affected vessel was unquestionably the cause of the aneurism.

μ. Permanent shortening of the *tendons* in the immediate vicinity of the stump is sometimes a source of great discomfort, as well as of serious interference with the usefulness of the limb. The accident is most liable to happen in the tendons of the hamstring muscles after amputation of the leg, and in the tendo Achillis after removal of the foot by Chopart's method. Much may be done, in both cases, in the way of prevention, by attention to position during the after-treatment: it is, in fact, the neglect of this precaution that usually occasions the difficulty. When the occurrence is unavoidable, or is already fully established when first brought under the notice of the surgeon, rectification is attempted, generally with a fair prospect of success, by the subcutaneous section of the shortened tendons, and the subsequent use of an extending apparatus, constructed on the

principle of the double inclined plane, with such modifications as may be required to adapt it to each particular case.

ν. The surface of an old stump occasionally suffers from *eczema*, coming on, perhaps, long after the amputation. The occurrence, which is most common in an imperfectly healed stump, is characterized by the formation of little blebs and chaps, cracks or fissures, the seat of a thin, pale, watery discharge, and of more or less itching. The most suitable remedies are cleanliness, conjoined with an occasional laxative, and the application of zinc ointment, dilute tincture of iodine, and solutions of acetate of lead. Occasionally nothing allays the itching so promptly and effectually as the use of cosmoline with the addition to the ounce of ten grains each of camphor and chloral. In obstinate cases gentle ptyalism may be required.

ξ. *Ulceration* of the stump from insufficiency of skin, violent inflammation of a diseased cicatrice, and other causes, is one of the most distressing of the secondary effects of amputations, keeping the parts tender and painful, and interfering with the use of an artificial limb. In the milder cases relief is afforded by the application of nitrate of silver, lotions of acid nitrate of mercury, and various kinds of unguents, along with leeches and scarifications. Occasionally great benefit is experienced from thorough vesication with cantharidal collodion. In obstinate cases I have sometimes been obliged to excise the ulcer, especially when it depended upon the presence of a badly healed cicatrice. When the bone is in a diseased, softened, or carious condition, the affected part must be removed at the same time, otherwise the operation will be of no avail.

Filling up the gap left by the removal of the ulcer with sound skin taken from the neighboring parts is sometimes advisable, although the operation is one necessarily attended with occasional failure. Indeed, such a result will almost be inevitable unless the bones are perfectly healthy, and the transplanted flap is very thick and large, properly secured in its new place, and well protected during the after-treatment. Skin-grafting, properly so-called, may occasionally prove serviceable under such circumstances.

Resection of the stump may be required when the bone is uncovered, or imperfectly protected by soft structures. The operation is easily executed, care being taken to keep the knife as closely as possible in contact with the bone during the necessary dissection, so as not to interfere with any important vessels and nerves. A similar proceeding may be required in case of caries, necrosis, or exostosis.

Reamputation will be necessary when the stump is so conical as to unfit it for the use of an artificial limb; when the soft parts are seriously diseased; when the bones are extensively thickened, necrosed, or carious; and, finally, as already stated, when the stump is the seat of incurable neuralgia. It is barely possible that an aneurism of the stump might also necessitate such a resort. The operation is performed upon the same general principles as the primary one, either in the continuity of the stump or at the nearest joint, as circumstances may demand. The result, of course, is not always favorable, especially when reamputation is performed near the trunk for the relief of a stump of the lower extremity.

ο. *Malignant* disease of the stump, in its primary form, is uncommon, but sufficiently frequent as a secondary occurrence. Primary carcinoma usually appears in the form of epithelioma, as the result of protracted irritation from the pressure of the artificial substitute, and pursues the same course as in other parts of the body. Secondary carcinoma may take place either upon the cicatrice of the stump or in the skin and connective tissue, the period of its occurrence varying, on an average, from six weeks to three months from the time of the amputation. The treatment, in favorable cases, is by excision or amputation; under opposite circumstances, by palliation.

SECT. VI.—CONSTITUTIONAL EFFECTS OF AMPUTATIONS.

The most common constitutional occurrences after amputations, especially of the larger limbs, are excessive prostration, traumatic fever, pyemia, congestion of the lungs, tetanus, retention of urine, and, as a secondary consequence, hectic irritation.

α. The *shock*, consequent upon amputation, is frequently extremely severe, and may be due, either partly or exclusively, to mere depression of the nervous system, caused by the extent, violence, and duration of the operation, to loss of blood, or to the effects of anæsthetic agents, or to all these circumstances combined. More or less nervous depression will almost necessarily occur during such an operation, however slight, but it generally passes off without any particular treatment, simply under the influence of repose, exposure to the air, and a drink of cold water. In the more severe forms of the affection,

however, it may endanger life by its long continuance or excess, and then demands prompt attention. The most appropriate remedies are, lowering of the head, so as to facilitate the flow of blood to the brain ; the administration of brandy and ammonia, and tincture of digitalis, by the mouth, if the patient can swallow, or by the rectum, or under the skin, if the power of deglutition is lost ; a full dose of morphia and atropia ; and sinapisms to the spine, extremities, and precordial region.

β. *Traumatic fever* generally sets in within from six to twelve hours after the operation, and will be violent or otherwise according to circumstances, of which the most important are, the extent of the previous shock and loss of blood, and the temperament, habits, and state of health of the patient. It is characterized by heat and dryness of the skin, flushed countenance, suffusion of the eyes, headache, restlessness, excessive thirst, rapid respiration, and a frequent, hard, and irritable state of the pulse, attended, when there has been much hemorrhage, by a peculiar jarring impulse. These symptoms, in the milder cases, will often speedily subside spontaneously, but under opposite circumstances they will require attention, and, if the surgeon is not fully on his guard, he will be very apt to do a great deal more than is either necessary or proper. The fact is, this is not unfrequently the critical point in such cases ; if we do too much, the patient is irretrievably gone, the consequence being death either from exhaustion, pyemia, erysipelas, or a low state of fever, which nothing can cure. Hence the greatest caution is to be observed ; the symptoms must be watched, and the utmost care must be taken that they do not deceive us by their violence, which is often feigned rather than real, and, therefore, extremely apt to entrap the unwary and inexperienced. In general, it will suffice to administer a mild aperient, as a little Rochelle salt, a Seidlitz powder, or citrate of magnesium, to sponge the surface frequently with tepid water, and to give cooling, acidulated drinks, which are always very grateful in such cases. If the fever threatens to be obstinate, a little antimony is prescribed, either alone or in union with morphia, to promote perspiration, allay the heart's action, and induce sleep. The lancet is scrupulously withheld, unless the symptoms are of extraordinary urgency, and the patient is very plethoric, without having been weakened by shock or loss of blood. Then a vein in the arm may be opened, and the effect of the stream carefully watched, the bleeding being arrested as soon as the pulse evinces signs of flagging.

Very often after amputations of the larger limbs, especially those performed for compound fractures and dislocations, gunshot wounds, and railway accidents, a low form of fever ensues, the system reacting badly, the countenance looking pale and haggard, the skin being icterode, cold, and doughy, and the pulse shattered, with great depression of spirits, and an utter indifference on the part of the patient as to his fate. It is difficult to say what the real condition of the system under such circumstances is, but the probability is that the disorder is mainly due to the loss of blood and nervous fluid consequent upon the excessive shock to the system at the time of the accident, heightened, perhaps, by the effects of the operation. However this may be, the system being depressed and withered, the issue is usually most disastrous, very few persons recovering, no matter what course may be adopted for their relief. The chief reliance must obviously be upon stimulants, as brandy, quinine, ammonia, and nutritious food, with opium to allay pain and procure sleep.

γ. Amputations, especially those of the thigh, are often followed by *retention of urine*, caused apparently, not by any actual paralysis of the bladder, but by a want of proper volition, the organ retaining its power, without the patient being able to call it into action. It usually supervenes within the first twenty-four hours after the operation, and seldom lasts less than two or three days, when it gradually passes off. From what I have seen of this affection, in this class of cases, I am not disposed to ascribe to it, as some have done, an inflammatory origin : that such a condition occasionally exists, is certain, but, in general, I am sure it does not. Knowing how frequent retention of urine is after this and other capital operations, the attendant should diligently watch for it, and promptly use the catheter, in the event of its occurrence.

δ. A not unfrequent event after amputation is *pyemia*. Experience shows that it is most to be dreaded in cases preceded by extensive shock to the system ; hence it is very common after gunshot, railway, and steamboat accidents, attended with extensive laceration of the soft parts, and after compound fractures and dislocations. Professor Ashhurst finds that of 3110 cases of amputation collected from the records of several hospitals, pyemia occasioned death in 30.1 per cent. of all the fatal cases, and in 9 per cent. of the entire number. The attack generally comes on within the first six or seven days, being ushered in by violent rigors alternating with flushes of heat, and followed by a bad state of the

stump, with aching pains in the limbs and joints, excessive thirst, restlessness, and a tendency to delirium even early in the disease. When the joints are involved, there is commonly an erysipelatous blush upon the overlying skin, with great tenderness on pressure and exquisite pain on motion. The case generally proves fatal in less than a week from its commencement, and examination after death usually reveals the existence of small and ill-defined abscesses in some of the internal organs, particularly in the lungs, liver, and spleen.

The treatment is by stimulants and tonics, such as brandy and milk, quinine, and opium, given in large quantity to support the rapidly sinking powers of nature. Mercury, in the form of calomel, is sometimes useful, and may be administered in doses of three grains every four, six, or eight hours, with a view to rapid but gentle ptyalism. The bowels are moved by enemas, all active purgation being inadmissible. Locally, the ordinary remedies are employed, generally only such as are of a soothing character.

ε. *Congestion of the lungs*, if not actual inflammation of these organs, is another effect of this operation, occurring either alone, or conjointly with pyemia, erysipelas, or an adynamic state of the system. It generally comes on in a slow and insidious manner, and is, therefore, liable to make serious, if not fatal, inroads before its true nature is suspected, none of the characteristic signs of pneumonia being present. The only way in which it is usually detected is by auscultation and percussion, or by the changes perceptible in the respiratory movements and sounds of the chest. These changes are generally most conspicuous in the lower and posterior portions of the lungs, where the greatest amount of blood, in debilitated states of the system, is, in obedience to the laws of gravity, most liable to accumulate, and, consequently, to produce the greatest degree of mischief. In most of the cases of pulmonary congestion that I have met with after amputation of the larger limbs, there was either an entire absence of pain and cough, or these symptoms were so trivial as, in themselves, to attract hardly any attention. The patient is able to lie upon his back or on either side, and it is not often that the respiration is materially hurried or embarrassed.

Dry cupping, rubefacients, and blisters are the most reliable local remedies, the system being supported with stimulants and tonics, aided by morphia and minute doses of tartrate of antimony and potassium. The prognosis is generally unfavorable, especially if the disease has made considerable progress and the patient is much exhausted.

ζ. The occurrence of *tetanus* after amputation is uncommon, especially in the more temperate regions of this and other countries. Mr. Curling, in his work on this disease, gives a table of 128 cases of traumatic tetanus, three of which only were caused by amputation. The affection is much more frequent in military than in civil practice, and is most liable to be produced in persons of a nervous, irritable temperament, in consequence of exposure to direct currents of cold air. A few years ago I lost a man on the third day after an amputation of the thigh, solely from this cause; he had been moved, during my absence from the hospital, to an open door, so as to allow the air to blow upon him in a full stream. I have known other cases that were induced in similar manner; and I refer to the fact in order to attract special attention to it. The treatment of this disease being discussed elsewhere, it is unnecessary to refer to it here.

η. *Hectic irritation* is observed only, or chiefly, as a secondary effect of amputation, being caused either by profuse suppuration, or by a poisoned state of the blood and solids, from shock, hemorrhage, or the absorption of pus. The symptoms are characteristic, and the treatment consists of such means as are calculated to sustain the flagging powers of the system, especially quinine and iron, with aromatic sulphuric acid, atropia, milk punch, and nutritious food.

SECT. VII.—ARTIFICIAL LIMBS.

The stump, after the cicatrization of the wound, gradually undergoes, as might be expected, important changes in its several structures, so as to adapt it the better for the various hardships which it is destined to experience in the daily routine of a business life, and especially for the support of an artificial limb. The muscles, deprived of the power of motion, soon become pale and wasted, and are eventually transformed into hard, dense, fibrous bands, entirely destitute of their primitive properties. The bloodvessels are obliterated as high up as their first large collateral branches, and converted into solid, rigid cords; the extremities of the nerves are expanded into bulbous masses, of an elongated, cylindrical shape, exhibiting more of a nervous than of a fibrous structure; and the ends of the bones are rounded off, and covered in by a thin shell of osseous

matter, which thus effectually closes the medullary canal, as seen in fig. 226. The subcutaneous fat gradually disappears, and the skin, unless habitually subjected to pressure, is rendered abnormally thin and sensitive. These changes are, of course, the work of time, and hence they are always more conspicuous in proportion to the age of the stump. In the forearm and leg, the ends of the two bones are always united, when the cure is perfected by a kind of osseous bridge.

Fig. 226.

Appearance of the Bony Stump after Amputation.

The period at which the stump may be in a condition for the reception and support of an artificial limb must necessarily vary according to circumstances; if the operation has been well done, and the cicatrization has gone on favorably, the substitute may be used as early as the sixth or eighth week, although in general it will be better to wait some time longer, inasmuch as too early a recourse to it will be likely to render the parts sore and sensitive, if not the seat of ulceration and severe pain. So much, indeed, is the patient's comfort influenced by attention to this point, that it is hardly possible to be too cautious respecting it. The stump should be tightly bandaged for several weeks previous to the application of the artificial limb, to promote the absorption of redundant material, and thus impart to it somewhat of a conical shape. Washing it well several times a day with a strong solution of tannic acid and alum will have the effect of hardening the integument, so as to moderate its sensibility and prevent excoriation.

Great improvement has been effected in modern times in the construction and adaptation of artificial limbs, and there is reason to believe that the inconvenience and suffering occasioned by their use are more frequently attributable to the misconduct of the surgeon than to the want of skill on the part of the manufacturer of the substitute. It has only been within a comparatively recent period that operators have hit upon the correct principles of making good and serviceable stumps. Allanson, upwards of three-quarters of a century ago, understood the subject much better than it has been understood since, if we except the last twenty-five or thirty years. He strongly insisted upon a long and well-shaped stump, and exerted himself with great ability, but in vain, to induce the profession generally to follow his example. The happy changes lately introduced into this department of operative surgery are, I believe, mainly due to the manufacturers of artificial limbs, who, with an ingenuity and perseverance worthy of so good a cause, have reduced the whole process to one of principles founded upon the study of anatomy and mechanical philosophy. It would be difficult to conceive of any apparatus more beautiful it its construction, or more admirably adapted to the end proposed, than the artificial substitutes manufactured in this country. Combining lightness with strength, and neatness with symmetry, they are worn with great comfort and satisfaction, and are apparently as perfect as any piece of mechanism of the kind can well be made. The joints, constructed on the principle of the ball and socket articulation, are situated at the proper points, and their surfaces move upon each other with great accuracy and facility, through the intervention of cords, wires, springs, and levers, the whole arrangement being a close imitation of the natural muscles and tendons, if not in shape, at least in position and function. The socket is made with special care, neatly fitting the stump in every portion of its extent, and is well padded to prevent friction and excoriation, the pressure being diffused over the entire circumference of the stump, while the extremity of the latter is perfectly free in the interior of the former. The annexed cut, fig. 227, affords a good illustration of this apparatus.

Fig. 227.

To enable the patient to wear his artificial limb with comfort and convenience, it is necessary that he should have a good, long stump, well covered, perfectly even, and of proper shape, being neither too square and fleshy on the one hand, nor too thin and conical on the other. A short, thick, ill-formed stump is a great evil, from which the patient can promise himself no good; on the contrary, it can hardly fail

to be a constant source of annoyance and pain, becoming sore and excoriated under the slightest exercise. The duty of the surgeon, therefore, is one of great responsibility, and cannot be discharged without properly weighing, in every instance, the probable consequences of the operation. When he has his choice, his invariable aim should be to make a long stump, so as to afford an abundant leverage and support for the artificial contrivance. In the leg and thigh its length should not, if possible, be less than nine or ten inches; hence the place of election, for the former, should be only about from three inches to three inches and a half above the ankle, and for the latter about the same distance above the knee. It is not always, however, by any means, in the power of the surgeon to select the point where he might otherwise cut off the limb, and he must then be contented in leaving as much substance as he can. If the leg is amputated very high up, the weight of the body may be supported upon the knee, especially if the patient's social position is such as to prevent him from wearing an expensive substitute, and this will be the more necessary because it is often very difficult, if not impossible, to preserve the straightness and flexibility of the joint in the event of a very short stump, on account of its incessant tendency to retraction and ankylosis. It is for this reason that some surgeons have advised amputation of the thigh just above the knee, when accident or disease interferes with the formation of a suitable stump below; but, if we consider the difference in the danger of the two operations, we should hesitate before we give our sanction to such counsel, not forgetting that the risk increases with every inch the nearer the knife approaches the trunk. In amputation of the thigh, the principal pressure of the artificial limb upon the stump is concentrated near the body, but care is taken not to apply any direct pressure to the perineum, lest it should produce excoriation.

After amputation at the hip-joint an artificial limb can only be worn with the aid of a gutta-percha stump, about ten inches in length, firmly secured around the pelvis by a broad, well-lined girdle. With such a contrivance very little difficulty is experienced in walking.

In amputations in children, the development of the limb is always partially arrested, so that, by the time the individual attains his full stature, it will be several inches shorter, as well as thinner, than its fellow of the opposite side. Now, surgeons in applying this knowledge to amputations of the inferior extremity, have advised that it should never be cut off below the knee, but at the lower third of the thigh, on the ground that, if this precaution be neglected, one knee will ultimately be elevated a considerable distance above the other, thereby imparting to the gait a peculiar grotesque appearance. Experience, however, has shown that amputation of the leg, even if the stump is only a few inches in length, instead of being an objection, is a decided advantage, the limb thus affording a much longer leverage than when it is cut off through the thigh, for the adaptation of the arti-

Fig. 228.

Fig. 229.

ficial substitute, the knee-joint of which can always be made to correspond, in situation, with that of the sound limb. Moreover, by adopting this procedure, the weight of the body, provided the stump is not too long, is supported upon the knee; another most important desideratum under such circumstances.

Dr. Bly, of Rochester, has devised an artificial limb, which, in addition to the ordinary qualities of such a contrivance, admits of lateral motion at the ankle, in imitation of the

natural joint, and is, in all respects, constructed upon strictly anatomical principles. The artificial leg of Dr. Byrd, of Baltimore, has the advantage of affording perfect ventilation to the inclosed stump, thus keeping it constantly at an even temperature through the process of insensible evaporation from the surface.

The annexed drawing, fig. 228, conveys a good idea of the artificial limb usually worn by the laboring classes after the loss of a leg or thigh. It may be made very light, and, if the stump be of proper length, affords an admirable substitute, the person being able to walk nearly with the same facility as in the natural state.

Various attempts have been made to construct artificial hands and arms, and there are now a great many of these contrivances in the shops, which, in point of neatness and adaptability, leave hardly anything to be desired upon the subject. Fig. 229 affords an illustration of such a limb.

SECT. VIII.—MORTALITY AFTER AMPUTATIONS.

The mortality from amputations is so much influenced by extraneous and intrinsic circumstances, and requires such a vast amount of statistical material for comparison and contrast, that it is extremely difficult, if not impossible, in the existing state of the science, to arrive at any satisfactory conclusions respecting it. It has long been known that the danger of the operation is always greater in proportion to its proximity to the trunk and the size of the limb. Hence, amputation of the leg is less hazardous than amputation of the thigh, and of the thigh in its continuity than of the thigh at the hip-joint. The mortality of the operation is also greater, as a general rule, in hospital than in private practice, in military than in civil practice, and in private practice in cities than in the country. Amputations on account of railway accidents are extremely dangerous, and are liable to be followed by the worst consequences, even in subjects perfectly healthy at the time of the accident, owing to the excessive tendency to mortification and pyemia.

The circumstances which mainly influence the mortality after amputation may conveniently be arranged into four classes, the first of which refers to the age, previous health, and social position of the patient; the second, to the causes necessitating the operation; the third, to the nature, seat, and extent of the operation; and the last, to the after treatment.

1. It will readily be granted that the condition of the *patient* at the time of the accident rendering amputation necessary must exert an important influence upon his fate. If he is old, broken in constitution, or in a state of poverty, so as to preclude the possibility of receiving proper attention after the operation has been performed, the chances are that he will die, either from shock, erysipelas, pyemia, or congestion of the lungs. The previous state of his health exerts no little influence upon the recovery; not, perhaps, however, to the extent that is generally imagined. A person who is in bad health at the time he is severely injured cannot be expected to bear the shock of an amputation with the same impunity as one whose health is good. The system, exhausted by previous suffering, is ill qualified in such a case to react favorably after the nervous depression consequent upon the operation.

Age also exerts considerable influence over recovery. Children generally bear amputation better than adults and elderly persons, being less subject to attacks of erysipelas and pyemia, and making a more rapid recovery. The parts, too, unite more frequently by the first intention. At the Hôpital des Enfants in Paris, Guersant, who annually performs from fifteen to twenty operations of this kind, including all the larger limbs, and also occasionally the hip and shoulder-joints, loses not more than one out of about nine cases, although nearly all are of a scrofulous character. He ascribes his extraordinary success mainly to two circumstances; first, a thorough preparation of the system, and, secondly, the use of an abundance of good, wholesome, and nutritious food immediately after the operation, on the well-known principle that children do not tolerate abstinence nearly so well as adults.

Notwithstanding the success of Guersant at the above institution, it is a well-known fact, a fact amply attested by the experience of surgeons in all parts of the world, that scrofulous children are usually bad subjects for amputation as it respects their ultimate fate. Many of them do well for some time after the operation, especially if they are properly fed and cared for; the wound often heals with surprising rapidity, and, for a time, everything looks uncommonly promising. By and by, however, perhaps at a comparatively early period, the wound breaks out afresh, the neighboring bones or joints become involved, the general health gives way, and the patient finally perishes of pulmo-

nary phthisis, meningitis, albuminuria, dropsy, general œdema, fatty degeneration of the liver, or some other disorder denotive of a vitiated and depraved state of the constitution.

Advanced age is eminently unfavorable to a good result, experience having shown that amputations in old persons, especially amputations of the lower extremities, almost invariably terminate disastrously.

The social position, or the habits and occupation of the patient, must materially influence the result of an amputation. The poor man cannot command the same care and attention as the rich; he often suffers for want of proper food and nursing, and even medicine, at a time, perhaps, when he is most in need of them, and there is no doubt that many patients perish from this cause alone that might otherwise be saved. Intemperance in eating and drinking, and unwholesome occupations, must necessarily produce a prejudicial effect upon the result.

2. The influence of the *causes* necessitating amputation has long been a subject of remark on the part of practitioners, both in private and public. Thus, it is an established fact that a person who undergoes amputation of one of the larger limbs on account of a severe injury, as a compound fracture, or a lacerated and contused wound, is much more likely to perish from its effects than one who loses a limb on account of chronic disease. The system, in the former case, deeply depressed by the shock of the accident, often reacts very slowly and imperfectly, and is, therefore, ill prepared for the approaching ordeal of another violent commotion, the effect of which is felt by every organ and tissue of the body. In disease, on the contrary, the constitution, although perhaps extensively implicated, has become inured to suffering, and, unless too much prostrated, will generally be immensely benefited by the removal of the offending parts. The chief exception to this rule is in malignant affections, in which, in consequence of the vitiated state of the solids and fluids, amputation is often followed, and that very rapidly, by the worst results.

3. In considering the probable result of a case of amputation, we must not forget to take into view the nature, seat, and extent of the *operation*. Experience has proved that, in civil practice, primary amputation is, other things being equal, a decidedly more dangerous procedure than secondary. The very fact that such an operation is required shows that the accident for which it is performed must have been a severe one, involving, perhaps, the most dreadful lesion of the bones, muscles, joints, and bloodvessels, with frightful depression of the nervous system. Now, it is surely impossible that a patient thus circumstanced should be in a favorable condition to submit to another violent shock, such as must necessarily attend the removal of the affected limb, within a short time after reaction has been established. The statistics, both of private and hospital practice, in America and Europe, are decisive upon this subject, proving, beyond the possibility of doubt, a greater mortality after primary than secondary amputations. Thus, of 456 primary amputations of the thigh, leg, and arm, performed in four American hospitals, 157, or 34.21 per cent., terminated fatally, while in 174 secondary ones the number of deaths was 73, or in the ratio of 41.95 per cent.

In military practice, on the contrary, the results of amputations are reversed, the primary being incomparably more favorable than the secondary. This has been the result of the experience of surgeons in all ages and in all countries since the invention of gunpowder. Larrey and Guthrie saved three-fourths of their cases after primary operations, and the returns of the British surgeons in the Crimea are of a similar character, although the rate of mortality here was considerably higher, owing to the fact that most of the wounds were inflicted with the conical ball; whereas in the campaigns of Bonaparte, and in the Peninsular war, they were made with the round ball, the effects of which are, as a general rule, much less destructive than those of the former. The observations of European surgeons in regard to the superiority of primary over secondary amputations were abundantly verified during our late war, on both sides of the line.

The differences between the results of primary and secondary amputations in civil and military practice are no doubt due to the circumstances under which they are performed and the causes which lead to their necessity. In the first place, there is generally less shock in injuries received on the field of battle than in those received in civil life. Secondly, the soldier usually submits to the removal of his limb with greater sang-froid than the civilian, and often glories in his loss, believing that the world will regard it as an evidence of his prowess and patriotism; whereas the latter finds in his misfortune nothing but regret and private calamity. Thirdly, the operation is commonly more promptly performed in military than in civil practice, delay, in the latter case, being frequently occasioned by the doubts of the surgeon and the interference of the patient and of his

friends ; and, lastly, a soldier has not much chance of recovery from an amputation, when, an attempt being made to save his limb, he is subjected to rough and tedious transportation, and is afterwards obliged, when the operation has been performed, to breathe the contaminated atmosphere of a crowded hospital, tenanted by persons borne down by similar accidents. Under such circumstances, the mortality from erysipelas, pyemia, and typhoid fever will, other things being equal, be much greater than in private practice. Faure, from these and other causes, lost 270 out of 300 secondary amputations consequent upon injuries received in battle.

The size and situation of the wound exert an important influence upon the recovery. Here again the statistics furnished by various authorities are most eloquent and decisive. They have conclusively established the fact, now regarded as a great general law, that the larger the wound is, and the nearer it is to the trunk, the greater is the danger to life. Thus, Malgaigne, in his statistics of amputations of all kinds in the hospitals of Paris, found that the mortality after the removal of the great toe was in the ratio of one to six, whereas that of one of the smaller toes was only as one to twenty-six. In amputations of the foot the proportion of deaths was about twenty-five per cent., of the leg fifty-six per cent., and of the thigh sixty-two per cent. These results have been abundantly verified by the statistics of other institutions, as well as by those of military and private experience, and they are full of interest as establishing a law, which should never, if possible, be violated.

The causes which induce this difference in the larger and smaller amputations are chiefly shock, hemorrhage, pulmonary congestion, septicemia, pyemia, erysipelas, profuse suppuration, and gangrene of the stump. Tetanus, too, is more frequent after the former than the latter, although the mortality from this affection is not great under any circumstances, especially in the more temperate regions of this and other countries. It is certainly not difficult to understand the reason why the removal of a large limb should be attended with so much more risk than that of a small one. In the former case, the patient has to contend not only with the shock of the accident necessitating amputation, which is often of itself almost sufficient to destroy him, but as soon as reaction is established he is subjected to another source of depression, perhaps almost equally great, from the operation, frequently involving copious hemorrhage, and liable to be followed by profuse suppuration and high febrile excitement, all tending to depress and exhaust the vital powers. In the latter, on the contrary, there is little or no shock, either from the accident or the operation ; the loss of blood is inconsiderable ; and the inflammatory effects, local and constitutional, are comparatively trivial. In short, there is no disorganization of the blood as there is in the former, and hence no predisposition to pyemia, or purulent infection, and pulmonary congestion, which are a source of so much mortality after the large amputations performed for severe injuries.

The result of an amputation may be materially affected by the situation at which the bone is divided. Experience has shown that, in the femur, tibia, and humerus, more particularly, the danger is much greater when the bone is sawed through its shaft than when it is cut off at its articular extremity, owing to the injury inflicted upon the endosteum, and the consequent liability of this membrane to diffuse suppuration, phlebitis, and erysipelas, followed, not unfrequently, by pyemia in its worst form.

4. Finally, it needs no labored argument to prove that the mortality from amputation must be materially affected by the nature of the *after-treatment*. That many persons perish after such an operation from sheer neglect, bad nursing, or bad surgical management, is a fact too well known to require comment. This is true both of private and of hospital practice, but the remark applies with increased force when it is made with reference to military practice, which, however well the surgical staff of an army may be organized, must often, from the very necessity of the circumstances in which the operations are performed, and the difficulty of conducting the after-treatment in a proper and satisfactory manner, be followed by the most disastrous results, many lives being lost that might, under more auspicious circumstances as to locality, comfort, and convenience, be saved. The state of the atmosphere, as it respects purity and temperature, the prevalence of epidemic diseases, mental depression, want of proper diet, severe depletion, and inattention to the dressings, all exert a more or less powerful influence upon the issue of such an operation. The crowded wards of hospitals in large cities, incessantly pervaded by foul air, are notoriously prejudicial to recovery after amputations ; gangrene, exhausting suppuration, erysipelas, and pyemia are the common lot of such patients, and the consequence is that many of them perish. Hence it is that private practice, especially that of the country, always shows a much more favorable result than that of large public

institutions, or that of large towns and cities. During epidemic diseases, the percentage of deaths from amputations always exhibits a great increase; for it is then that patients are particularly prone to erysipelas, pyemia, and congestive pneumonia. Starvation and depletion are a serious source of mortality after this operation, establishing, as they do, a tendency to purulent infection and to a typhoid state of the system, from which often no stimulants, however powerful and well directed, can afterwards rouse it. I regard such treatment after amputation of a large limb, as, indeed, after every other capital operation, as a great evil, and one which, in my judgment, demands thorough reform on the part of our civil and military practitioners. Finally, I may mention, as another source of mortality, want of attention to the dressings, which, if allowed to remain on too long, not only taint the surrounding atmosphere, but favor the absorption of pus, much to the detriment both of the part and system.

Statistics.—I subjoin the following summary of the statistics of amputations performed at the Pennsylvania, New York City, Massachusetts General, and Boston City Hospitals, because it seems to place the whole subject of the mortality after these operations in a clear and satisfactory light. The table was constructed by Dr. James R. Chadwick, of Boston, and embraces the results of 1370 cases, of which 384, or 28 per cent., proved fatal.

	PRIMARY TRAUMATIC.				SECONDARY TRAUMATIC.				PATHOLOGICAL.			
	Recovered.	Died.	Total.	Ratio of mortality.	Recovered.	Died.	Total.	Ratio of mortality.	Recovered.	Died.	Total.	Ratio of mortality.

The most extended statistical tables of amputations, both primary and secondary, that have yet been furnished, are those of Mr. James R. Lane, of London. They embrace an aggregate of 5722 cases, derived from various sources, civil and military, private and hospital, European and American, and may, therefore, be regarded as exhibiting a very fair view of the mortality after these operations in different parts of the world.

		2067	819		1451	540		587	259	

In the American Journal of the Medical Sciences for October, 1867, Dr. S. W. Gross published the statistics of 13,514 amputations for gunshot injuries, and since that date he has materially added to the number, as will be seen from the subjoined table, comprising an aggregate of 20,933 cases, derived principally from the late military hospitals of the United States, the Austrio-Prussian campaign of 1866, and the wars in the Crimea, Schleswig-Holstein, and Italy.

Amputations for Gunshot Injuries.

Amputations of the Superior Extremity.	Total.	Recovered.	Died.	Percentage of deaths.
Wrist-joint .	176	125	51	28.97
Forearm .	2462	1954	508	20.62

	9518	4210	5308	55.76
	20,933	12,495	8438	40.30

The comparative death-rate of limb-amputations in metropolitan and provincial hospitals, in large and small hospitals, and in hospitals and private country practice in Great Britain, was placed in a very striking point of view in 1870 by the researches of the late Sir James Y. Simpson. The results obtained by him may be arranged in tabular form.

Hospital.	Beds.	Amputations.	Recoveries.	Deaths—Ratio.
Metropolitan .	300 to 500	2089	1134	855 or 1 in 2.4
Provincial .	200 to 300	803	575	228 or 1 in 3.5
"	100 to 200	1370	1069	301 or 1 in 4.4
"	26 to 100	761	627	134 or 1 in 5.6
"	25 or under	143	123	20 or 1 in 7.1
Private practice .	. . . .	2098	1872	226 or 1 in 9.2
		6264	5400	1764 or 1 in 3.5

The results of the tables of Mr. Lane show, it will be perceived, in their aggregate relations, a mortality of 36.92 per cent., or one death in every 2.7 persons subjected to operation. Of the 1370 cases in the four American hospitals, 384 died, giving a mortality of 28 per cent., or one in every 3.5. Of the 6264 amputations analyzed by Sir James Y. Simpson, 1764, or 28 per cent., proved fatal, thereby affording a ratio of one in 3.5; while the mortality after amputation for gunshot injuries was 40 per cent., or one in every 2.48 cases.

CHAPTER XIX.

EXCISION OF BONES AND JOINTS.

THE term excision serves to denote the removal of a bone, whether in its continuity or at its extremity, whether it be limited to a portion of its extent or embrace its totality. When only the head of a bone is concerned in the operation, the word decapitation is occasionally used, and, as meaning the same thing, some authors have adopted the name of exsection, while others, especially the French and German surgeons, employ that of resection. Excision differs from amputation in this, that, while in the latter the bone is removed along with the soft parts which surround it, in the former the bone alone is cut away, the integument, muscles, and other tissues being retained, in order that they may contribute to the future usefulness of the limb; or, in other and more comprehensive language, while in the one case all the structures are destroyed, in the other as many of them as possible are preserved. Hence this department of surgery has very appropriately been denominated conservative surgery, and it is most gratifying to know that it constitutes one of the leading characteristics of the healing art of the present day. It is not to be expected that excision of the bones and joints will ever entirely supersede the necessity of amputation, for so long as the various tissues of the body are subject to disease and accident, so long will they require removal by the knife in order to prevent the extension of their effects; but that the frequency of the operation will eventually be greatly diminished, the experience of the last twenty years abundantly attests. Conservative surgery is still in its infancy, and it is needless to conceal the fact that it will take a long time to determine its legitimate limits.

Although incidental mention of excision of the bones occurs in the writings of some of the earlier surgeons, yet it is probable that, if such an operation was ever performed by them, it was in great measure, if not entirely, limited to the removal of the protruding ends of fractured bones. However this may be, it is certain that there is no well-authenticated case of excision of the heads of any of the bones until 1762, when Mr. Filkin, of Northwich, removed those of the knee-joint. Soon after this a similar service was performed for the superior extremity of the humerus by Vigaroux, David, and White. In 1781, Mr. Park, of Liverpool, repeated Filkin's operation, and, from the gratifying success attending it, he was led to propose its extension to all the principal articulations, much to the surprise of most of his contemporaries, who looked upon the measure as harsh and reckless. The consequence was that the procedure met with much opposition, and it might even have been entirely lost sight of if it had not been for the boldness and skill of Moreau, the elder, of Bar-sur-Ornain, who, towards the close of the last century, exsected, in rapid succession, the articular extremities of the shoulder, knee, and elbow. The success of the French surgeon was followed up by that of his son and successor, who obtained great celebrity for his operations upon the joints, attracting patients from all parts of France, and who, at various intervals, embodied the results of his observation and experience in separate monographs addressed to the Academy of Surgery at Paris and other learned societies. In the early part of the present century excision of the joints received a powerful and salutary impulse from the French army surgeons, particularly Larrey, Percy, Willaume, and Bottin, who repeatedly performed extirpation of the articular extremities of the bones, especially those of the shoulder, on account of gunshot injury. The operation, indeed, was performed, at one time, upon a large scale, and many limbs, as well as lives, were doubtless saved by it. Notwithstanding this, however, the procedure was generally regarded with suspicion in Great Britain, where, although it originated there, it made no actual progress until about fifty years ago, when, chiefly through the example of

Liston, Syme, and Ferguson, it began to attract universal attention among medical men. During the last third of a century the operation has been performed in numerous instances, by surgeons of the highest eminence, upon all the principal articulations, and the results have been such as to show that this department of the healing art now rests upon a solid and immutable basis. In this country excision of the joints was, until recently, greatly neglected, both in hospital and private practice : this, however, is no longer the case, for, since the civil war, the intelligence, zeal, and skill of our surgeons have nowhere been displayed to greater advantage in this branch of the healing art. All innovations require time for their adoption, and what De Condillac said of another subject is equally true of this. "Il est rare que l'on arrive tout-à-coup à l'évidence : dans toutes les sciences et dans tous les arts, on a commencé par une espèce de talonement."

Excision of the bones in their continuity has been practised, for various purposes, for a long time, and modern surgery is indebted to it for many of its most brilliant exploits. It is in this department, more particularly, that American operators have displayed their greatest skill. Commencing with excision of the inferior jaw by Dr. Deadrick, of Tennessee, in 1810, we may with just pride point to the operations of Mott upon the clavicle, of Mussey, McClellan, and Gilbert upon the scapula, of Butt and Carnochan upon the ulna, and of the latter upon the radius, not to mention numerous minor cases, which, although less known, have reflected the highest credit upon the scientific character of the profession, and conferred the greatest benefit upon a class of sufferers who would otherwise have been doomed to loss of limb and life.

The principal circumstances necessitating excision are, disease of the bones and joints, as caries and necrosis, gunshot, railway, and other injuries, and various kinds of deformity. The existence of malignant disease in or around an articulation contraindicates its performance. Excision has often been advantageously practised in ununited fractures, and it is also occasionally resorted to for the relief of deformity dependent upon ankylosis.

The most common cause for which excision is employed is caries of the bones, more especially of their articular extremities, and the operation, if properly executed, is generally followed by the most gratifying results, not only as it respects the life of the patient, but the usefulness of the limb. The operation is particularly adapted to chronic cases, in which the morbid action is in great degree arrested, and the system has become inured to suffering. Under opposite circumstances, it is liable to lead to disastrous effects, and should, therefore, if possible, be avoided.

In compound fractures and dislocations excision has been practised almost from time immemorial, and frequently with the most satisfactory results. In the latter of these accidents in particular, whether involving the large or small articulations, experience has shown that it is generally more safe, both as it respects limb and life, to resect the ends of the protruded bones than to restore them in the usual manner. In the ordinary reduction, the synovial membranes and cartilages are usually rapidly destroyed ; profuse suppuration takes place, and the patient gradually sinks under hectic irritation ; or if, after having struggled through the general danger, he at length escapes with his life, he is very liable to lose his limb, or, at all events, to have a permanently stiff, deformed, and useless joint.

Statistics of excisions for gunshot injuries will be given in a future chapter. Here I shall only observe that extended experience has demonstrated that the only large joints to which the procedure is at all applicable are the wrist, elbow, shoulder, and ankle. Performed upon the hip and knee, it is either promptly fatal, or so unsatisfactory as to require subsequent amputation.

Instruments.—Various instruments are required for the ready and successful performance of this operation, and it is always desirable to have rather too many than too few, so that every emergency may be promptly met as it arises. The incisions through the skin and muscles are made with ordinary scalpels, but for detaching the bones from the soft parts and dividing the ligaments, stout, probe-pointed knives, with broad steel handles, convex and semisharp at the end, will be necessary. Excision of the bone is effected with a hand-saw, a pair of pliers, or the gouge and chisel, according to the structure, size, and situation of the affected piece. The saw, which may be a common amputating one, should be from six to ten inches in length by three to twelve lines in width, its teeth being sharp and widely set, and its handle long and thick. A saw introduced by Mr. Butcher, of Dublin, and bearing his name, will be found very useful, especially when there is but little space, or when it is necessary to divide the bone obliquely. It has, as will be perceived by a reference to the engraving, fig. 230, a very narrow blade, the angle of which can be changed at pleasure. In addition to these instruments, it will be well to have upon the tray a Hey's saw, fig. 231, and also a very narrow concave saw, fig.

232, with a blunt end, in the event of its being necessary to divide the bone from behind forwards. As to the chain saw, fig. 233, even in its most approved forms, it may well

Fig. 230.
Butcher's Saw.

be dispensed with, as its use is generally only productive of delay, vexation, and disappointment. Bone forceps or pliers, figs. 234-35-36, usually known as Liston's,

Fig. 231.

Hey's Saw.

Fig. 232.

Curved Saw for Small Bones.

although long ago described and delineated by Scultetus, should be at hand, of various shapes and sizes, as they may frequently be employed with great advantage in places

Fig. 233.   Fig. 234.   Fig. 235.   Fig. 236.
Chain Saw.   Bone Forceps.

where it is impossible to introduce and work the saw. The surgeon should also be provided with several gouges and chisels, a strong mallet, trephines, scrapers, and a large

elevator, together with a thick leather strap or leaden spatula for protecting the soft parts, during the division of the bone, suitable instruments for holding the flaps apart, and a syringe for washing out the wound or clearing away sawdust and the debris of diseased bone and cartilage.

The different steps of the operation will be greatly facilitated by the use of the elastic bandage, which, if skilfully applied, will render the proceeding completely bloodless. The ordinary tourniquet is not only unnecessary but absolutely hurtful by damming up the blood in the recent seat of the diseased structures. If proper care be taken, there will be no danger of laying open any of the larger arteries, none certainly that may not be readily secured by ligature.

Position of the Patient.—The position of the patient, the surgeon, and the assistants, as well as the number of the latter, varies in different cases and under different circumstances, and does not admit of any precise rules. Generally speaking, the recumbent posture will be the most suitable, especially if an anæsthetic is given and the operation is at all likely to prove tedious. In cases of any magnitude, as in exsection of the knee-joint, the number of assistants should not be less than five or six ; one administering the anæsthetic, two holding the limb, one handing instruments and tying arteries, and another having charge of the sponges.

As it respects the operation itself, it may conveniently be considered as consisting of three stages, the division of the soft parts, the excision of the bone, and the dressing of the wound.

Incisions.—In planning the incisions, care must, of course, be taken not to interfere with any structures, the division of which might compromise in any way the result of the operation. The sheaths of the tendons are to be especially avoided. To lay them open would be to invite inflammation and plastic deposit, which could not fail to impair their usefulness. The nervous trunks are turned aside, out of harm's way, and the larger vessels, both arterial and venous, are studiously protected from injury.

The number and direction of the incisions will necessarily vary in different cases. In most cases, even in such large joints as the hip and shoulder, a single longitudinal cut, either straight or more or less curvilinear, will be quite sufficient for the purpose. Langenbeck, who has acquired great distinction in this field of surgery, seldom employs any other incision than the simple longitudinal, and his success, as is well known, has been very extraordinary. Operations in which the parts are exposed by flaps of a semilunar, square, or horseshoe form, are seldom practised at the present day, it having been found that the wound is much longer in healing, and that the danger from erysipelas, pyemia, and other bad consequences is greatly increased. Incisions made after the manner of some of those depicted in the chapter on minor surgery will afford the surgeon an opportunity of adapting his operations to any case that will be likely to come under his observation.

The elliptical incision may be adopted, when it is necessary to remove diseased integuments, but, in any event, the great rule is to sacrifice as little soft substance as possible. Even when the flap is very large and unseemly, it must not be retrenched, experience having proved that it will always contract down to the proper dimensions during the progress of the cure. In separating the bone from its muscular and ligamentous connections, the knife must be kept as close as possible to its surface ; any deviation from this rule will be likely to be followed by the division of structures which should not be meddled with, especially important bloodvessels.

Removal of the Bone.—Insulation of the bone having been effected, it is next to be pushed through the wound, and excised, the parts around being carefully protected from injury by a piece of leather or a metallic spatula placed underneath. Whenever it is feasible, I prefer sawing off the bone to cutting it away with the pliers, as the surface thus made is more smooth, as well as less bruised, and, consequently, more liable to heal well. In operating upon the smaller bones, as those of the carpus and tarsus, we are generally obliged to make free use of the gouge and chisel. In whatever manner the excision may be accomplished, the invariable rule is to cut through the healthy structure ; and this is applicable even when the bone is merely denuded of its periosteum, observation having shown that, when the osseous tissue is divested of its natural covering, it is either already dead, or must soon die. In excision of the long bones, the condition of the medullary canal and its contents should always be carefully scrutinized, with a view of ascertaining whether the part should be still further retrenched or not. Imperfect excision is worse than useless, as no thorough cure can take place after it without another operation. Finally, when two bones require to be removed, as, for example, in excision

of the tibia and fibula, they should be sawed off upon the same level, otherwise the limb will be apt to be forced to one side, and so be rendered comparatively worthless.

In excision of the joints, none of the capsular ligament should be left, experience having shown that the danger from inflammation is materially increased when this precaution is neglected.

With the regard to the periosteum, the rule of practice is to preserve every particle not involved in disease. Of the value of this precept there can be no question, seeing what an important part this membrane plays in the formation, nourishment, and reproduction of the osseous tissue. In the chapter on diseases of the bones an instrument is represented which I have long employed for effecting the separation of the periosteum, and which is admirably adapted to such an object. It is a good plan always to raise the attachments of the muscles and tendons along with the periosteum, as its vitality is thus less likely to be interfered with. After the operation is over, the membrane should be thoroughly unfolded, and carefully spread over the surface of the wound.

In cases of long standing, requiring excision, the periosteum is generally very considerably thickened, and, therefore, comparatively easily detached, the reverse being true in excision performed in accidents and in cases of recent disease, in which the greatest care and patience are usually required to enable one to accomplish the object.

Dressing.—Bleeding having been arrested, the wound is washed out with cool water thrown in with a large syringe, in order to get rid of the sawdust, which, if allowed to remain, would act as foreign substance, liable to provoke suppuration and erysipelas, if not worse consequences. Any sinuses that may exist are also pared or laid open. The edges of the wound are then approximated by the interrupted suture and adhesive plaster, aided, if necessary, by a compress and bandage. The most dependent portion of the wound, however, should always be kept patent by means of a small tent or tube, to favor drainage. If this precaution be neglected, the result will be that the secretions, which are always more or less profuse after such an operation, will accumulate in the wound, thus not only impeding the cure, but often inducing necrosis of the bones, and affording an opportunity for the easy entrance of pus into the system.

Before the patient is returned to bed, the limb should be placed in the position in which it is to rest during the after-treatment, and kept perfectly quiet by means of appropriate apparatus. In excision of the inferior extremity osseous union is usually desired, as the limb would hardly be useful without it, and, hence, it will not be proper, as a rule, to make passive motion. In the upper extremity, however, this rule is not applicable; here motion is both sought for and attained at all hazard, an ankylosed wrist, elbow, or shoulder being of little value.

The great sources of danger, after excision of bones and joints, are excessive suppuration, pyemia, septicemia, hemorrhage, and erysipelas. These accidents are to be carefully guarded against by the ordinary means, and treated upon general principles in the event of their occurrence. If the convalescence is unusually protracted, and especially if the wound is slow in healing, if sinuses form, or if there is much discharge of an unhealthy character, there will be reason to suspect that the bones have again become diseased, and that further interference will be required before a cure can finally be effected.

The twitching of the muscles after these operations, so often interfering with the reparative process, and causing the patient intolerable anguish, is generally very promptly relieved by hypodermic injections of morphia, or by morphia and valerian administered by the mouth.

Statistics.—The statistics of excision of the bones and joints have been placed in a very prominent and satisfactory point of view by the researches of Dr. Richard M. Hodges, of Boston, and by Dr. Oscar Heyfelder, of St. Petersburg, in two excellent and exhaustive monographs, published in 1861. The subjoined tables, compiled by the latter of these writers, comprise the aggregate results of 2241 cases, of which 1280 relate to the bones, and 961 to the joints.

Excision of Bones.

	Cases.	Recoveries.	Deaths.	Failures.	Percentage deaths.
Extremities	605	471	60	74	9.91
Face	559	379	174	6	31.12
Trunk	116	82	32	2	27.58
	1280	932	266	82	36.04

Excision of Joints.

	Cases.	Recoveries.	Deaths.	Failures.	Percentage deaths.
Wrist	49	35	9	5	18.36
Elbow	286	205	32	49	11.18
Shoulder	196	131	30	8	15.30
Ankle	174	149	16	9	9.19
Knee	213	129	64	20	30.04
Hip	70	35	35	...	50
	961	684	186	91	36.78

From these tables it will be seen that in excision of the joints the smallest mortality is afforded by the ankle, and the largest by the hip. In regard to excision of the bones, the greatest percentage of fatal cases is furnished by the face. The mortality after all amputations, according to Mr. James R. Lane, calculated from a total of nearly 6000 cases, is as high as 36.92 per cent., or one in every 2.7 of the patients submitted to the operation.

Dr. S. W. Gross has collated the most extensive statistics of excision of the shafts of the bones for gunshot injuries, of which I have any knowledge. The subjoined table, compiled by him, comprises 1657 cases.

Excision of Bones.

	Cases.	Recoveries.	Deaths.	Percentage deaths.
Radius	359	311	48	13.37
Ulna	312	262	50	16.02
Radius and ulna	64	56	8	12.50
Humerus	700	496	204	29.14
Fibula	81	65	16	19.75
Tibia	72	57	15	20.83
Tibia and fibula	19	15	4	21.05
Femur	50	6	44	88
	1657	1268	389	23.47

In a recent exhaustive work on excision of the joints for gunshot injuries, Professor Gurlt, of Berlin, has analyzed 3667 cases, the results of which, as are shown in the following table, were determined in 3596.

Excision of Joints.

	Cases.	Recoveries.	Deaths.	Percentage deaths.
Wrist	132	112	20	15.15
Elbow	1403	1054	349	24.87
Shoulder	1634	1067	567	34.70
Ankle	145	94	51	35.17
Knee	144	33	111	77.08
Hip	138	16	122	88.40
	3596	2376	1220	33.92

It will thus be perceived that in excision of the long bones the smallest mortality is afforded by the radius and ulna, and the largest by the femur. In regard to excision of the joints, the smallest percentage of deaths is afforded by the wrist, and the largest by the hip. The aggregate mortality of the above cases is 30.63 per cent., while of the 20,933 amputations for gunshot injuries, according to Dr. Gross, 8438, or 40.30 per cent., proved fatal.

CHAPTER XX.

ANÆSTHETICS.

THE prevention of pain in surgical operations has been an object of anxious solicitude with practitioners from time immemorial, and we accordingly find that suggestions, more or less plausible, have been made at different periods with a view of meeting this important end. One of the most remarkable of these suggestions, inasmuch as it was a clear foreshadowing of the anæsthetics of the present day, occurs in the surgical writings of Theodoric, in the latter part of the thirteenth century. The means recommended by him consisted in thoroughly impregnating a sponge with a strong aqueous extract of various anodyne articles, especially opium, hemlock, hyoscyamus, lettuce, and mandragora, and then after having been immersed for an hour in warm water, holding it to the nose until the patient fell asleep, when the operation was proceeded with. In order to rouse him when the operation was over, another sponge, dipped in vinegar, took the place of the " spongia somnifera," as the former was denominated; and, if this expedient failed, the juice of the root of fenugreek was freely injected into the nostrils. In India, the extract of the hemp plant, cannabis Indica, indigenous to that country, has been employed for the same purpose for ages past. Near the close of the last century, great hopes were entertained that a successful agent had at length been found in the inhalation of nitrous oxide gas, either alone, or variously combined with other vapors; but after numerous experiments, in which Sir Humphry Davy and other eminent philosophers took an active part, the project was at length abandoned as chimerical. Some time prior to this period, Mr. Moore, of London, had suggested the possibility of diminishing pain in surgical operations, especially in amputations, by compression of the principal nerves, by means of an instrument, somewhat similar to a tourniquet, but so constructed as to constrict the limb only at two points, one of the pads being regulated by a screw. The experiment was tried at St. George's Hospital, by John Hunter, upon a man whose leg was cut off below the knee on account of a large, irritable ulcer of the foot, and the suffering is said to have been exceedingly slight. Very few, however, seemed inclined to repeat it, and the consequence was that it was soon given up; a result which might have been anticipated by the originator of the plan, as the instrument used for the compression was not only uncertain in its operation but productive of great uneasiness during its application.

In 1819, Mr. James Wardrop, of London, proposed to diminished the sensibility of the patient in surgical operations by means of copious venesection, and in a paper which he published on the subject in the tenth volume of the Medico-Chirurgical Transactions he cites several cases illustrative of its beneficial influence. He thought the practice particularly adapted to persons of a nervous, irritable temperament, and he recommended that it should be carried to the extent of syncope, so as completely to annul all sensation during the dissection. In one of his cases, he bled the patient, a young, robust woman, to fifty ounces before he began the operation, which consisted in the extirpation of a small tumor from the orbital plate of the frontal bone, during which she remained perfectly unconscious, expressing great surprise when she found it was over. As might have been expected, however, she remained very weak for several days after the operation, although she made a rapid recovery. I am not aware that this recommendation met with any particular favor.

The administration of the different preparations of opium for the purpose of lessening the pain in surgical operations is an old practice, highly lauded by some, and as greatly condemned by others. I was myself in the habit of employing it for many years in almost every case that fell into my hands previously to the discovery of anæsthetics: I generally preferred morphia to laudanum or opium in substance, and always gave it in full doses, either alone, or, when the patient was strong and plethoric, combined with a moderate quantity of tartrate of antimony and potassium, with a view of inducing a greater degree of relaxation and insensibility. I became very fond of the practice, and never, so far as I could determine, experienced any bad effects from it; on the contrary, I know that it

was commonly productive of great benefit, not only blunting sensibility but preventing shock, and, consequently, severe reaction.

Notwithstanding these various attempts to prevent suffering in surgical operations, no anæsthetic agent, using the term in its legitimate sense, was discovered until 1844, when Dr. Horace Wells, a dentist of Hartford, Connecticut, wishing to have a tooth extracted, rendered himself completely insensible by inhaling nitrous oxide gas; and he soon afterwards administered the same remedy to several of his patients with effects equally gratifying. Shortly after this, Dr. Wells repeated his experiment before the medical faculty and students of Harvard University at Boston, but, owing to mismanagement either in the apparatus or the gas itself, the attempt signally failed, and the only reward which he received for his pains was ridicule, which, in his case, was the more cruel, because he was a man of uncommon sensibility. Two years later, Dr. Morton, also a dentist, and a pupil of Wells, resorted to the inhalation of sulphuric ether, first in his own person, and afterwards in some of his patients, until he became convinced that it might be taken not only with impunity, but with the most perfect certainty of preventing pain in any operation, however severe or protracted. Fortified with this knowledge, he applied at the Massachusetts General Hospital, at Boston, for permission to repeat his experiments upon a man who was about to undergo an operation for the removal of a tumor of the neck by Dr. John C. Warren. The result was everything that could have been desired. The next day, Morton etherized a patient for Dr. Hayward; and the news of the remedy rapidly spreading, its use soon became general, both in the United States and in Europe. In the latter country the subject attracted perhaps even greater attention than at home, and soon led to the discovery of chloroform by Sir James Y. Simpson, of Edinburgh, in 1847. Various other articles possess anæsthetic properties, as chloride of hydrocarbon, nitrate of ethyl, aldehyd, benzin, the Dutch liquid—a compound of chlorine and olefiant gas—kerosoline, bisulphuret of carbon, amylen, protoxide of nitrogen, and bichloride of methylene, but, with the exception of the last three, it is questionable whether any of them are sufficiently innocuous to justify their exhibition.

Practically it is of no importance to know who the discoverer of anæsthetics was; but, if we carefully inquire into the history of the matter, we cannot fail to award to Dr. Wells the credit of having made the first successful application of this class of agents for the prevention of pain during a surgical operation. Nearly fifty years previously, Sir Humphry Davy had, it is true, employed nitrous oxide gas for the relief of a severe headache, brought on by the intoxication caused by the rapid drinking of a bottle of wine for experimental purposes, and afterwards as a means of preventing the pain in cutting the gum over a wisdom tooth; but, as every one knows, no further use of the remedy was made until it was resumed by Dr. Wells, and applied with express reference to the production of anæsthetic effects. He was beyond doubt the first to establish the possibility of preventing pain in surgical operations; and had his experiments at Boston not eventuated in chagrin and disappointment, he would unquestionably have pushed his researches much further, and perhaps speedily hit upon the very articles which were afterwards found by Dr. Morton and Professor Simpson to possess such valuable properties. To both the latter gentlemen the world owes an immense debt of gratitude for having brought to light the wonderful anæsthetic effects of ether and chloroform.

In an article in the Virginia Medical Monthly for May, 1877, J. Marion Sims has furnished evidence going to show that sulphuric ether was first intentionally employed as an anæsthetic in surgical operations in 1842, by Dr. C. W. Long, of Athens, Georgia. The only circumstance invalidating this claim is the persistent silence of Dr. Long and his friends during the long and heated controversies growing out of the labors of Wells, Morton, and Jackson. Hence, although he may have been, and probably was, the first to use this fluid as a means of preventing pain, he failed to interest the profession in it, and has thus lost all just claim to the honor of one of the greatest discoveries ever achieved by human genius.

It is not a little singular that the two countries in which the anæsthetic virtues of ether and chloroform were discovered should each, respectively, have preferred for many years its own remedy; America ether, and Great Britain chloroform. There are, however, in Great Britain, many surgeons who now employ ether, and in this country many practitioners who prefer the latter article, both in surgical and obstetrical practice, and I have myself constantly used it ever since its introduction among us in 1848, believing it to possess decided advantages over ether, although its administration unquestionably requires the greater care and attention. Among the more important of these advantages are, first, the more rapid manifestation of the anæsthetic action of the remedy, the system becoming

affected much sooner, as a general rule, than it does by ether; secondly, a smaller amount of laryngeal and bronchial irritation; thirdly, the more easy maintenance of the anæsthetic influence, after the system has once been fairly affected; and, lastly, the less liability to cause vomiting and other unpleasant consequences. The very odor of ether is to many persons excessively offensive, and there are very few in whom the inhalation does not produce more or less cough and vomiting. On the other hand, it certainly requires less caution in its administration, and thus far it has furnished but few deaths, whereas the mortality from chloroform is already above three hundred. Dr. Maddin, of Nashville, who has carefully investigated the subject, finds that most of the fatal cases of anæsthesia have occurred in minor surgery, or in operations of a comparatively trifling nature, and in which, consequently, the remedy might probably have been entirely dispensed with. For a number of these cases the dentist is accountable, nearly all the earlier and not a few also of the later having happened during the extraction of teeth, from the want of precaution in not sufficiently depressing the head during the operation.

It is remarkable that many of the fatal cases have occurred in private practice, or in small institutions, a circumstance which would seem to show that there had been some fault in the mode of administration of the remedy. At Guy's Hospital, London, chloroform had been employed in upwards of 12,000 cases before there was any serious accident; in the war in the Crimea, according to the testimony of Flourens, it was administered more than 25,000 times without a single death; and during the late war in this country there were, according to Dr. George A. Otis, only 8 cases out of upwards of 120,000 in which a fatal result could fairly be attributed to its use. Dr. J. S. Wellford, of Richmond, ascertained that, in the Confederate army, during the same period, chloroform was used in 22,000 cases without any accidents, and only one death in 15,000 cases is recorded by Professor Hunter McGuire.

From statistics collected from fourteen hospitals in London and Liverpool, in 1867, it appears that chloroform was administered in 83,059 cases, of which 24, or 1 in 3461, proved fatal. In the eye department of Guy's Hospital this article was employed, up to 1870, in 3221 cases without a single death, although 45 of the patients became blue in the face and suddenly stertorous, with irregular pulse and breathing.

Professor Andrews, of Chicago, in 1870, collected from different American and European hospitals the statistics of 117,078 cases in which chloroform was administered, with 43 deaths, affording thus a ratio of mortality of 1 to 2723. Of 92,815 cases, obtained in a similar way, of etherization, only four perished, or 1 to 23,204. A mixture of chloroform and ether was employed in 11,176 cases, of which only 2 died, the mortality being as 1 to 5588. Of the results of the administration of bichloride of methylene, all we know is that, up to 1872, in 7000 cases there had been only a few deaths.

In the hands of certain surgeons, the use of chloroform, as an anæsthetic agent, has been attended with astonishing success. I have now administered it in all kinds of operations in several thousand cases without a single death, and in only three cases did I feel any serious alarm for the safety of the patient. Syme gave it in about 5000 cases without any serious occurrence, and Simpson, it is said, met with only one death in all his immense experience. Professor Nussbaum, of Munich, in 15,000 cases, never lost a patient; and Billroth had no deaths in 12,500 cases. The results of the experience of other practitioners are equally gratifying. It is to be regretted than an agent capable of conferring such vast benefit should be so little employed in this country, because a fatal instance, produced, for the most part, by maladministration, is occasionally reported, as if death in surgical operations never arose from any other cause.

I ascribe my own success in the use of chloroform to the extraordinary care with which it has been administered in my practice, to the proper selection of my cases, and to the pains which have always been taken to procure a pure article, preference having generally been given to Squibb's preparation. An assistant who is accustomed to superintend the inhalation of chloroform is far safer than an inexperienced one, and neither in hospital nor private practice should any other ever be permitted to meddle with it.

It has been asserted by the opponents of chloroform that the rate of mortality in the great operations of surgery has been essentially increased since the introduction of that article into practice, and Mr. Arnott, of London, has taken pains to collect elaborate statistics with a view of establishing the fact upon an irrefragable basis. On the other hand, the statistics of Sir J. Y. Simpson, the discoverer of the anæsthetic properties of chloroform, go to show that the number of deaths is not only not increased, but absolutely diminished. Perhaps the truth lies between these two statements. Dr. Macleod, in his Notes on the Surgery of the War in the Crimea, published in 1858, declares it as his

conscientious belief that the use of chloroform in the British army saved many lives, and that numerous operations were performed by its assistance which could not otherwise have been attempted. It is not improbable that, if there has really been an increase in the mortality after operations since the introduction of anæsthetics, it has been owing, not to the pernicious effects of the remedy, but to the fact that surgeons have been emboldened to undertake operations in cases which were formerly regarded as unfit for the employment of the knife, and, above all, to the circumstance that of late years there has been a fearful increase of railway and other terrible accidents, many of which are necessarily fatal, no matter to what treatment they may be subjected.

Dr. Henry W. Davis, of Illinois, in a paper in the Chicago Medical Examiner for 1862, declares that chloroform, judiciously administered, so far from being a depressant, in severe shocks from gunshot injury, is a powerful stimulant, rapidly raising the pulse, and soon followed by healthy reaction. He states that he could cite numerous instances, presenting every degree of severity, but all attended with extreme prostration, in which the exhibition of this agent produced the most happy effects, and he adds that no amount of exhaustion, however intense, would induce him to withhold it, provided the lesion is recent. The experience of Dr. Davis has been confirmed by other observers, and I have myself seen a number of cases illustrative of the truth of his statements.

Anæsthetics not only prevent pain and mental suffering, but by placing the patient in a passive condition give the surgeon a control over him which he could not possibly obtain in any other manner. Deprived of sensibility and consciousness, the former is virtually dead to all external impressions, and permits the surgeon to conduct his dissections and other manual processes with as much ease and deliberation as if he were operating upon the cadaver. The advantages thus gained are absolutely incalculable, and he who would fully appreciate them must be able to put himself in the twofold situation of patient and surgeon, and then, in imagination, contrast their condition with that of the patient and surgeon of former times, before the discovery of anæsthetics, when the one was writhing in pain and agony during a tedious dissection, and the other had his progress incessantly interrupted by the cries and struggles of the sufferer.

The exhibition of anæsthetics is important not merely as a preventive of pain, but also as a means which enables us to investigate our cases more thoroughly prior to an operation. Exploration of the bladder, formerly a source of so much suffering, is now performed without the slightest uneasiness, and the same is true of stricture of the urethra, diseased bones, affections of the anus and rectum, and various other lesions. The use of anæsthetics affords immense advantages in the examination of dislocations and fractures, permitting us to handle the parts more satisfactorily, and, therefore, to form a more correct diagnosis.

There are some operations in which the use of anæsthetics is usually regarded as inadmissible; thus, in harelip, the excision of the tongue, and removal of the jaw, the patient, as a general rule, should be under the influence of these remedies only at the beginning of the procedure; after the dissection has been fairly commenced, he should be sufficiently conscious to enable him to coöperate with the surgeon, otherwise the blood, passing down into the windpipe, might cause severe cough and other inconvenience, seriously embarrassing him. The same remark applies to excision of the tonsils, although I have frequently removed these glands while the patient was so far under the influence of chloroform as to render him incapable of offering any resistance. Extirpation of the jaw I have repeatedly performed under similar circumstances, passing through the different stages of the operation while the person was in a state of perfect unconsciousness. Even the more delicate operations upon the eye, as the establishment of an artificial pupil, and the extraction of cataract, may be safely performed with the aid of anæsthetics, although, as it respects the latter, it should not be forgotten that the vomiting which occasionally attends their use might destroy the organ.

It has been asserted that one advantage of the use of anæsthetics is that it diminishes the liability to hemorrhage during an operation, but I have never been able to satisfy myself that this is true; nor have I any reason to believe, as has been so frequently alleged, that there is greater danger of secondary hemorrhage after the employment of these agents, due to loss of tone in the smaller vessels and to a decrease of coagulability of the blood. Both opinions are without proof.

Chloroform.—Chloroform, a terchloride of formyl, is a clear, colorless liquid, very volatile, of an agreeable, aromatic odor, of a pungent, saccharine taste, very dense, of the specific gravity of 1.500 at 60° Fahr., almost insoluble in water, non-inflammable, and perfectly neutral, neither reddening nor bleaching litmus paper. It is a compound

of three atoms of carbon, one of hydrogen, and three of chlorine. Various impurities are liable to be mixed up with it, especially the chlorinated pyrogenous oils, ether, and alcohol. The presence of oils is readily detected by pure, strong sulphuric acid, to which they impart a change of color, varying from yellowish to reddish-brown, according to the quantity of the extraneous substances. A still more simple test consists in pouring the suspected fluid upon the hand, where, rapidly evaporating, it deposits its oily impurities, which are easily recognizable by their offensive smell. Dropped upon white paper, pure chloroform speedily disappears without leaving any stain. The existence of alcohol is detected by dropping a small quantity of chloroform into distilled water; if pure, it will retain its transparency at the bottom of the glass, if not, each globule will acquire a milky appearance. The presence of ether may be detected by the inflammable character of the fluid. It is practically important to know that chloroform deteriorates by exposure to heat and to a strong light. The most reliable article is prepared with methylated spirit.

There are five principal circumstances which should be closely attended to during the exhibition of chloroform, and, if this be done, it will be difficult, unless the article is bad, or the patient has some idiosyncrasy, to produce any unpleasant effects with it. These are recumbency, an empty state of the stomach, a free play of the diaphragm, an abundance of atmospheric air, and a gradual administration.

1st. During etherization the patient may sit up with impunity, but this is not the case during the inhalation of chloroform, owing, apparently, to the greater relaxation of the muscles, and, consequently, to the increased difficulty in maintaining the circulation of the brain through the influence of the heart's action. Lying upon the side, when this is practicable, is perhaps the safest posture of all, as the breathing will then be less likely to suffer by the falling back of the tongue. The head should never be much raised, nor the neck bent.

2d. An empty state of the stomach is desirable for two reasons; first, because if chloroform be given soon after a heavy meal it will almost certainly induce vomiting; and, secondly, because a crowded condition of the organ interferes materially with the movements of the diaphragm. Food must not be taken for at least four hours before the exhibition; but, on the other hand, the interval should not be too protracted, lest serious exhaustion result from the want of necessary stimulus.

3d. Care must be taken, before the inhalation is commenced, that the patient's clothes are sufficiently loose to prevent constriction of the chest and abdomen. Any compression from this source would necessarily impede the action of the diaphragm, and might thus become a cause of mischief.

4th. The importance of having an abundance of atmospheric air during the inhalation of an article so potent as chloroform is self-evident; in etherization this is of comparatively little consequence, but in the exhibition of chloroform for surgical and obstetrical purposes it is absolutely indispensable to the safety of the patient.

5th. The inhalation must be effected gradually, not hurriedly, time being allowed the system to accommodate itself to the influence of the remedy, thus avoiding the shock which might otherwise be inflicted upon the heart and brain. From three to eight minutes should usually be spent in producing the full effects of the anæsthetic.

6th. When the patient is very feeble, or pale and timid, it will be advisable to give him immediately before the operation, from half an ounce to an ounce of brandy; and the dose may afterwards be repeated, if the effect is obliged to be maintained for an unusual length of time, sufficient consciousness being permitted for the performance of deglutition.

7th. It is a good plan, as a rule, to administer about an hour before the operation is begun a hypodermic injection of morphia to quiet the nervous system, and shorten or avert the stage of excitement, sustain the action of the heart, and prevent laryngeal and bronchial irritation. This has been my practice for many years at the College Hospital as well as with my private patients, and I have found no reason to regret it. Indeed I am satisfied that it not only adds greatly to the safety of the patient, but that it also renders anæsthesia possible with a less quantity of chloroform than is required under ordinary circumstances. Bonwill's method of rapid respiration also exercises an obtunding effect on the air passages, and may often be beneficially employed when the use of an anodyne is not deemed advisable or proper.

The best mode of administering chloroform is to pour the fluid upon a napkin or handkerchief, previously folded into a cone or cup-shaped hollow, and held securely in the hand. Or, instead of this, a small hollow sponge may be used. As to the various

inhalers that have been devised for the purpose, most of them are objectionable on account of their inconvenience and the difficulty of obtaining a sufficiency of atmospheric air. One of the best of these contrivances is that devised by Professor Chisholm, of Baltimore, used extensively in the Southern States during the late war. It consists of a metallic instrument, fitted for insertion into the nostrils, the mouth being left entirely free for breathing. In this way, anæsthesia is rapidly induced without any waste of fluid from evaporation even in the open air. The apparatus of Dr. Skinner, of Liverpool, a very simple and efficient one, consists of a wire frame in the shape of a shallow ladle covered with flannel, the concavity being held over the nose and mouth while the chloroform is dropped upon the convex surface. The apparatus of Mr. Clover, so extensively employed in London, is too troublesome and expensive for general use.

The patient having taken his place upon the table, and emptied his lungs by a deep and protracted expiration, the napkin, impregnated with a drachm of chloroform, is held over the mouth and nose, at a distance of about two inches, being gradually brought nearer and nearer until it is within one-fourth of that distance, beyond which it should not be carried, the chest being at the same time regularly and powerfully distended. The pungent effect of the liquid upon the skin should be prevented by anointing the face with some protective unguent, otherwise vesication may arise. All unnecessary conversation is avoided, lest the attention of the patient should thereby be unduly distracted. The assistant having charge of the administration gives it his earnest and undivided care, wetting the napkin from time to time with the fluid, and seeing that the patient obtains an abundance of air, his vigilance increasing as the effects of the medicine become more and more apparent. As soon as the sensibility is completely abolished, the operation is commenced, a return to consciousness being prevented by holding the napkin, sprinkled with a small quantity of the vapor, occasionally before the nose, and thus the impression is maintained, steadily and cautiously, not only until the knife has fully accomplished its object, but until the principal arteries have been secured, and, in some cases, even until the dressings have been applied.

As soon as the inhalation has been fairly entered upon, an attendant should sedulously watch the pulse, respiration, and countenance. If any sudden change be noticed in their condition, the administration must instantly be discontinued, or, if persisted in, conjoined with a more liberal supply of atmospheric air. It is not necessary that a finger should be constantly kept upon the pulse; for the color of the face and the nature of the breathing will always sufficiently indicate the effects which the anæsthetic is exerting upon the system, and thus afford abundant opportunity for preventing any unpleasant occurrence.

When chloroform acts as a decided depressant, as in excessive anemia, organic disease of the heart, or inordinate exhaustion from profuse discharge, the anæsthetic effect should be maintained with ether, experience having shown that, if it be not, in such an event, a positive antidote to the evil consequences of chloroform, it restores the force of the circulation, and may be administered without the slightest risk to life.

The quantity of chloroform required during an operation, and the time during which its effects may be safely maintained, must, of course, vary according to the exigencies of each particular case. In general, from half an ounce to an ounce may be regarded as a fair average, but very frequently it takes three, four, or even five times that amount, depending upon the severity and duration of the operation, and the susceptibility of the individual. In some instances almost an incredibly small portion answers the purpose. Children usually require comparatively little; and it is well known that women are generally more susceptible to its influence than men. Persons exhausted by hemorrhage are very easily affected by it, owing to the rapidity of its absorption, and hence it should always be administered to them with unusual care. In obstetric practice, the effects of chloroform may be maintained, with impunity, for many hours together, and the same remark is true of severe and tedious surgical operations. Thus, in an attempt to reduce a chronic dislocation of the shoulder-joint, I kept the patient steadily under the influence of the remedy for two hours, during which not less than twelve ounces were consumed.

Age is no bar to the use of anæsthetics. I have given chloroform repeatedly to very young children, and, in several instances, with excellent effect, even to infants under two months. In fact, the more tender the age is, the more easy is the induction of insensibility. Old persons also bear the inhalation well. On one occasion I gave it with the most gratifying effects to a lady of ninety-two, supposed to be laboring under a fracture of the neck of the thigh-bone. Certain diseases are very properly regarded as contraindicating the employment of chloroform, particularly organic lesions of the heart, lungs,

and brain, anemia, and the habitual use of intoxicating drinks. It should never be administered in cases of accidents attended with severe shock or loss of blood until after thorough reaction has taken place. In administering chloroform to infants and very young children, only a few drops should be poured upon the napkin at a time, and care should be taken to hold the cloth at a considerable distance from the mouth and nose, so that the fluid may enter the lungs well diluted with atmospheric air.

Effects.—The effects of chloroform upon the system may, for practical purposes, be divided into two stages, that of excitement, and that of insensibility. The first begins soon after the commencement of the inhalation, and is characterized by various cries and struggles, as if the patient, feeling alarmed, were anxious to escape from the table. The face becomes flushed, the eye has a wild and staring expression, the pulse is preternaturally frequent, and the mind is incoherent; as the effects increase, the brain falls into a species of exhilaration closely akin to that of intoxication. It is now that the individual usually exhibits his peculiarities of temperament and habit. Thus, if he is of a boisterous disposition, he will be apt to be noisy, to swear, or to fight, and to make the most violent efforts to disengage himself from the assistants. One man will laugh and joke; another will weep, or moan and sigh; the sportsman will fancy himself occupied in the pleasures of the chase; the wily craftsman, in driving a good bargain; the lawyer, in addressing a jury; the preacher, in exhorting his congregation; and the physician, in prescribing for his patient. The mind is in a dreamy, perverted condition, and whatever is most predominant at the time in thought and feeling is sure to exhibit itself in expression.

This excitement varies much both in degree and duration; in many cases it is very slight and transient, while in some it is even entirely wanting, the patient being perfectly tranquil throughout. When considerable, it is very liable to be reproduced, to a greater or less extent, as the effects of the remedy wear off, so that the individual will, perhaps, be quite as boisterous after the inhalation is over as he was soon after its commencement. In very nervous, excitable persons the intoxication may last for several hours, although this is uncommon.

In the second stage, which succeeds imperceptibly to the first, the individual gradually lapses into a state of entire unconsciousness; the muscles, thoroughly relaxed, are no longer under the control of the will, the limbs retaining any position in which they may be placed; the eyelids are closed and the balls turned up, the pupils being contracted, and insensible to light; the respiration is calm and easy; and the pulse is soft and undisturbed, or, if at all changed, it is rather below than above the normal frequency. Feeling and intellection are suspended, and everything indicates that the patient is in a quiet and pleasant sleep, wholly unconscious of surrounding objects, and, therefore, completely insensible to pain. If this state be carried a little further, coma will arise; the patient will snore as if he were apoplectic, the pulse and respiration will diminish in force and frequency, and the pupil will become notably dilated. As yet, all is safe, but a few more whiffs, and an important link in the chain of life may give way, and the patient be sent into eternity. In the administration of chloroform we should always strive to prevent coma. The most unexceptionable form of anæsthetization unquestionably is that in which there is a perfect suspension of sensibility without the complete abolition of consciousness; but it need hardly be added that it is, practically, extremely difficult to produce such a nice result in any case. In general, the patient, on recovering from the effects of the remedy, has no distinct recollection of anything that passed while he was under its influence.

The effects of chloroform seldom completely disappear under several hours. After the more characteristic symptoms have subsided, the mind will still be somewhat bewildered, the muscles relaxed, and the feelings perverted. In some cases, especially in children, the patient, after having passed through a most severe operation, will fall into a tranquil sleep, and, perhaps, not wake fully for an hour or two. In other cases, again, the effects go off very rapidly, and the individual will be roused not only to a state of consciousness, but to severe pain. When the vapor is very freely employed, there will frequently be some degree of nausea or even vomiting, either during the operation, or at its close, upon the return of consciousness. Emesis is most common in children and in persons of a nervous, irritable temperament, but may generally be entirely prevented by the administration of a little brandy or whiskey immediately before the inhalation of the anæsthetic is commenced. Headache, although infrequent, is occasionally met with, and may last for a number of hours. It is most liable to occur when impure chloroform is used.

I have never witnessed any permanently ill effects from the exhibition of chloroform, such as partial paralysis, loss of sensation, or perversion of taste and smell; and a similar

declaration has been recorded by the late Dr. Snow, of London, in his work on Anæsthetics, published in 1858.

Although chloroform is one of the greatest boons which a kind and beneficent Providence has bestowed upon man for the prevention and alleviation of pain, yet, like every other remedy, it is capable, when abused, or injudiciously administered, of producing the most deadly effects. These effects are those of a narcotic poison; and as they may follow, in persons of unusual susceptibility, the inhalation of the smallest quantity of the liquid, it is of the utmost importance that they should never, for a moment, be lost sight of in the use of the article. An overdose may destroy life almost instantaneously, or death may occur at a variable period after the exhibition; sometimes even after partial reaction has taken place. The phenomena indicative of danger are, stertorous respiration, a small, feeble pulse, lividity of the features, dilatation of the pupils, relaxation of the sphincters, and rapid diminution of the temperature of the body.

Death by chloroform may occur in at least four different ways, by coma, by asphyxia, by syncope, and by gastric irritability, as it effects the brain, the lungs, the heart, or the stomach. Dr. J. C. Reeve, of Ohio, who, in 1867, was at great pains to investigate the causes of death from the inhalation of this fluid by the examination of a large number of recorded cases, is of opinion that the fatal event is not unfrequently produced by mere shock, in the same manner as in a blow upon the stomach, or as when a draught of cold water is taken in an overheated state of the body.

Death by coma generally occurs suddenly, apparently from the absorption of the chloroform, and its direct sedative effect upon the brain; or, as is more probable, upon the brain and spinal cord. The occurrence is always preceded by stertorous breathing, by lividity of the surface, and by convulsive movements of the muscles, the action of the heart ceasing with the respiration, or even before the respiration is completely extinguished. Elderly persons, worn out by intemperance, protracted disease, and the depressing passions, are most subject to this mode of death.

In death by asphyxia the breathing stops suddenly, the heart continuing to beat for a short time after all motion of the chest has ceased. The occurrence is denoted by the gasping character of the respiration, the lividity of the features, the distension of the jugular veins, the flickering nature of the pulse, and the dilated and insensible condition of the pupils. Death takes place, not directly from the effects of the chloroform, but indirectly from deprivation of oxygen, the anæsthetic not having been admixed with a sufficient quantity of air during its inhalation.

In death by syncope from an overdose of chloroform the fatal event is due to paralysis of the heart, or the sudden abstraction of nervous fluid, the patient dying very much as in shock, induced, perhaps, only by a very few inhalations. The heart ceases to beat before the breathing, the countenance is of a ghastly, livid hue, the pulse is weak and flickering, and life is usually destroyed very suddenly. Persons with a soft, flabby heart, accompanied with fatty degeneration of its muscular structure, and dilatation of the left ventricle, are most liable to suffer in this way.

Death from gastric irritability does not occur suddenly but gradually, not perhaps under several days, the primary impression being apparently made upon the pneumogastric nerves, and the secondary upon the brain, heart, and lungs. The event is uncommon. In a typical case, a very remarkable one of its kind, observed by the late Dr. Thomas Wood, of Cincinnati, the very first inhalation produced retching, followed by vomiting before the patient became insensible; the anæsthesia was maintained for half an hour, and, on the return of consciousness, the gastric trouble reappeared, and continued until the close of life on the sixth day. The retching and vomiting, in this case, were evidently, in the first instance, entirely independent of any cerebral disturbance, although, in its progress, both the brain, the lungs, and the heart became seriously implicated, as is shown by the fact that at the end of twenty-four hours there was delirium, with tremulous movements of the muscles, dilatation of the pupils, and lividity of the general surface, symptoms which steadily persisted up to the time of death. When a person, after having been comatose or asphyxiated, partially recovers, he may linger for several hours, or even a much longer period, in a state of partial unconsciousness, and finally die under all the symptoms of profound congestion of the brain and lungs, with a tendency to serous effusion and deposits of lymph; or he may gradually regain his health, without, perhaps, any bad ulterior effects.

The repeated inhalation of chloroform does not seem to establish a tolerance of the remedy, or to serve as a security against a fatal occurrence. A very considerable percentage of the recorded deaths by this agent took place during the inhalation for the

second, third, or fourth time.   To produce a fatal effect, it is not necessary that the quantity of chloroform should be large or that the inhalation should be at all protracted. Frequently a few hurried whiffs are sufficient.   Of 102 cases of death from chloroform, tabulated by Sansom, in which the stage of anæsthesia was noted, 50 perished before the full effects of the remedy were produced.

When death ensues from these trivial causes, the probability is that the event is generally dependent upon extraneous circumstances, as the idiosyncrasy of the individual, the amount of shock or loss of blood, exhaustion from disease, an overloaded state of the stomach, the semierect posture, mental emotion, and other untoward conditions of the system, not always appreciable before the inhalation is begun.   The baneful influence of fear in debilitating the system is well known ; and it is not to be forgotten that a person, although pretty completely influenced by chloroform, may suffer violently from shock induced by a severe and protracted operation.

Treatment.—The treatment for the relief of the poisoning consequent upon an overdose of chloroform must be prompt and efficient ; for everything depends upon the surgeon's presence of mind and the rapidity and energy with which he applies his remedies.   The first thing to be done is to desist from the further administration of the remedy ; the second, to place the head below the general level of the body, and to draw the tongue out of the mouth with a towel or tenaculum, so as to lift it away from the glottis ; the third, to cause a full access of cold air, by throwing open the doors and windows of the apartment, and making free use of the fan ; the fourth, to dash cold water upon the body, or still better, to pour it from a height of several feet ; the fifth, to institute artificial respiration, by introducing a tube into the windpipe and percussing the body, or blowing air into the mouth ; the sixth, to stimulate the surface, especially over the spine and heart, with hot mustard water, lotions of veratria, or dilute spirit of hartshorn ; the seventh, to administer an injection of turpentine ; and the last, to apply galvanic electricity, passed through needles inserted into different parts of the body, more especially over the heart, diaphragm, and spine.   A lump of ice inserted into the rectum often produces an excellent effect.   "Flipping" the surface with the end of a towel wrung out of cold water is a powerful excitant.   As soon as the patient is able to swallow, free use is made of brandy and ammonia.   These means should be employed with great diligence and regularity until it is perfectly evident that life is irrecoverably extinct.

Striking the patient with the flat hand, sharply and rapidly, upon all parts of the body —the face, trunk, arms, and legs—is worthy of trial.   The clothes, as a preliminary step, should be removed as speedily as possible, and the efforts should be uninterruptedly continued until there is a return of breathing and pulsation.   Accoucheurs often resort to this process of reviving stillborn children ; it is a powerful stimulus making its primary impression upon the sensitive nerves of the skin, and through them, by reflex action, upon the spinal cord, the heart, and the capillaries.   Striking the surface gently and rapidly with small switches, or the end of a fringed towel wrung out of ice water, is often of great service ; and there is, according to my experience, no more powerful excitant than a strong solution of veratria rubbed freely and roughly upon the back and chest. Mouth to mouth insufflation is also a very valuable method of resuscitation in chloroform poisoning.   To render it effective, the larynx should be pressed against the spine, to prevent the air from passing into the œsophagus, and the insufflation should not be performed too rapidly or too forcibly, lest the lungs be injured.

The late Professor Nélaton, of Paris, under a conviction that death from the use of chloroform is due to syncope or anemia of the brain, strongly recommended inversion of the body, thus rendering the head the most dependent portion, and at the same time keeping up steady artificial respiration.   Numerous cases successfully treated by this method have been recorded by different observers, and there is no longer any doubt respecting its efficacy.

The inhalation of the vapor of ten to fifteen drops of nitrite of amyl has frequently proved successful in restoring the heart's action, and the agent should always be in readiness whenever chloroform is exhibited.

For the minor effects of chloroform very little is necessary, beyond a discontinuance of the inhalation, sprinkling the face and chest with cold water, allowing a free access of cold air, and passing a smelling bottle rapidly to and fro under the nose.   If any lividity exist, indicative of impending asphyxia, the tongue must immediately be pulled out and steadily held till the breathing is fully reëstablished.

If vomiting occur, the patient must instantly be turned upon his side—not on his abdomen, lest the action of the diaphragm be impeded—with the head inclining down-

wards, otherwise the contents of the stomach, as they are lazily ejected from the œsophagus and fauces, might easily descend into the larynx, and thus induce suffocation. When the gastric distress is obstinate or protracted, the best remedies are brandy and a hypodermic injection of morphia.

In women, the unconsciousness, consequent upon the inhalation of chloroform, sometimes continues so long as to cause serious alarm for the safety of the patient. Such apprehension, however, is generally groundless, experience having shown that, when this state lasts beyond half an hour, it is due to hysteria, and not to the effects of the anæsthetic. Sometimes convulsions are induced, but they always promptly subside under the continuance of the inhalation.

Anæsthetics should never be administered to women except in the presence of witnesses. The cases of the two dentists, the one of this city and the other of Montreal, which some years ago created so much excitement both in and out of the profession, show that no man's character, however pure or exalted, may altogether escape censure, if, indeed, ruin. The remarkable instance which, a few years ago, occurred at the Philadelphia Hospital, of a woman who, while under the influence of anæsthesia, went through all the movements of the sexual congress, and analogous examples reported in the medical journals, clearly prove how strongly the imagination of the patient may be impressed in this way, while thus affected, and how vividly the idea may remain after the ordinary effects have passed off.

Ether.—The administration of sulphuric ether may be effected with a large, broad sponge covered with soft leather, with a towel inclosed in a thick paper cone, or, what is far better, and much more economical, with the inhaler of Dr. Oscar Allis, of Philadelphia, or of Dr. Lente, of New York, the latter of which is represented in fig. 237. The apparatus essentially consists of a bottle, a gum-elastic tube fitted with a stopcock, and a light, helmet-shaped framework, covered with two layers of flannel. Upon inverting the bottle and holding it above the mouth-piece, the ether diffuses itself very rapidly, the quantity used at the commencement of the operation being about two drachms, succeeded by three more as soon as the patient begins to respire fully, the effect being thus maintained until complete anæsthesia is induced. When the inhaler is removed from the face, as when stertorous breathing ensues, it must be placed on its base, to prevent the escape of vapor. The quantity of ether consumed does not, ordinarily, exceed two or three ounces, and from four to five minutes usually suffice to effect the desired object.

Fig. 237.

Lente's Inhaler.

When the inhalation is effected with a sponge or towel, not less than half an ounce of ether should be used in the first instance, and the administration should be steadily continued until the full object is attained, which often occupies from five to ten minutes. No particular attention need be paid to the admission of atmospheric air, as this fluid possesses none of the poisonous properties of chloroform. The quantity of ether consumed in this mode of administration is seldom, in ordinary cases, less than from four to eight ounces, while in the more protracted, twice or even thrice that amount may be necessary.

The first effect of the inhalation of ether is usually a short, hacking cough, but this soon subsides, and the system gradually lapses into a calm, quiet condition, attended with muscular relaxation, closure of the eyelids, and mental obliviousness, followed, in many cases, especially if the head lie low, and the tongue be permitted to fall back, by stertorous respiration. Sickness and vomiting are common occurrences; and occasionally there are spasmodic or tetanic movements, the body being thrown forcibly and convulsively backwards, as in opisthotonos. After the patient recovers his consciousness he often complains of severe headache, sometimes lasting upwards of twenty-four hours. Moreover, the breath usually retains for a long time, occasionally, indeed, for several days, the disagreeable odor of the anæsthetic.

In administering chloroform, the patient must always be recumbent; in etherization, on the contrary, he may sit up, or recline, as may be most convenient to the operator, no injury resulting even from the protracted maintenance of the erect posture. The inhalation, too, may be carried on more rapidly, and, as already stated, without any special

reference to the admixture of atmospheric air, a sufficiency always entering through the inhaler. Any bad effects that may arise from etherization should be treated upon the same general principles as those produced by an overdose of chloroform. The cold douche, in particular, will be of much service in recalling the patient to consciousness. The head should be depressed and the tongue drawn out if there be stertorous breathing, and the patient rolled upon his side and the ether withheld, if there be spasmodic, tetanic, or convulsive movements of the body. All the different varieties of ether possess anæsthetic properties; but the one universally preferred is the sulphuric, thoroughly washed, and divested of impurities. It is the article which Dr. Morton originally introduced to the notice of the profession under the name of letheon, or pain-destroyer, and which is now so much employed in surgical and midwifery practice in this country.

Some practitioners prefer a mixture of ether and chloroform to either of these articles alone, considering it to be equally efficacious, and at the same time more safe. I have myself frequently employed them in this way, and regard the combination as unobjectionable in every respect. The ordinary proportion is three parts of sulphuric ether to one of chloroform; but the quantity of either agent may be increased or diminished, according to the exigencies of the case, or the whim, fancy, or caprice of the surgeon. A mixture of equal parts of chloroform and alcohol was recommended by Dr. Snow, and is generally regarded as a very safe and efficient anæsthetic. In administering it to very young children, it may be diluted with rectified spirit, although, if proper care be taken, this is not at all essential, either to safety or convenience. Dr. Washington L. Atlee used one part by measure of chloroform and two of pure sulphuric ether in 300 ovarian operations without a solitary loss. The "Vienna Mixture," as it is termed, is made up of six parts of ether and two of chloroform; and has been administered in 8000 cases without one fatal result.

The committee appointed by the Medico-Chirurgical Society of London, in 1864, to examine into the merits of different anæsthetics, arrived at the conclusion that the safest way to administer chloroform is to combine two parts of this article with one of pure alcohol and three of concentrated ether. The superiority of this mixture is due, the committee allege, to the stimulating influence of the alcohol, and to its modifying effect upon the rate of evaporation of the two other constituents. The perfect safety of the mixture when properly administered, is fully attested by the experience of many of the best practitioners both at home and abroad.

In administering ether for surgical purposes in which the hot iron or galvanic cautery is employed, as, for instance, in operations about the face, mouth, or jaws, great caution must be exercised, otherwise the fluid, which is a highly inflammable one, may burn the patient or ignite his clothing. The flame of a lamp held in close proximity to the vapor is especially dangerous.

How the inhalation of ether proves fatal has not been decided. When death occurs promptly, as during, or very soon after, the administration, the probability is that it is caused by asphyxia, whereas when it occurs at a later period, as after the lapse of hours or days, there is reason to believe that it is due to the effects of congestion of the brain and lungs, either alone, or in conjunction with gastric irritability, which often exists in a most distressing degree. The number of deaths occasioned by the administration of ether is by no means inconsiderable. Hence the greatest caution should be used when employed as an anæsthetic. Old, sickly subjects, especially such as labor under fatty degeneration of the heart, seem to be most liable to suffer from its depressing effects. Lividity of the countenance or sterterous breathing imperatively demand the prompt suppression of its administration and the employment of restoratives.

Ethyl Bromide or Hybromic Ether, a compound of bromine, alcohol, and ether, is an anæsthetic that was at one time largely used by the late Mr. Nunneley, of Leeds, and subsequently strongly recommended by Dr. Richardson, of London. An atmosphere containing from eight to ten per cent. of the vapor causes, when inhaled, rapid reduction of the common sensibility, the pulse and breathing remaining tranquil, and the expression of the countenance good. Owing to the rapid transition from the first to the third stage of narcotism, there is little, if any, muscular excitement. No apnœa occurs, and the recovery is usually very prompt. An attempt was made a few years ago, in this city, by Dr. Laurence Turnbull and Dr. Richard J. Levis, to recall the attention of the profession to the use of this substance as an anæsthetic agent; but, owing to several deaths, occurring in pretty quick succession from its exhibition, it has again fallen into disrepute as a safe and reliable article, and it is not at all likely that it will ever again be aroused from its slumbers.

Bichloride of Methylene.—Bichloride of methylene, or chloromethyl, as it may be more properly called, was introduced into practice, as a general anæsthetic agent, in 1867, by Dr. B. W. Richardson, who administered it for the first time to the human subject in October in that year, in a case of ovariotomy performed by Mr. T. Spencer Wells. It possesses many of the properties of chloroform, but differs from it in having a sweeter odor, in being more pleasant to inhale, and in containing one atom more of hydrogen and one atom less of chlorine. It resembles ether in being inflammable in air. As an anæsthetic it causes less excitement than chloroform, is not so liable to produce vomiting, is more persistent in its action, and does not provoke rigidity of the muscles of the jaw, or lividity of the countenance. The sleep is usually very gentle, and with proper care may be maintained without injury for any reasonable time. Complete narcotism may be induced with from one and a half to three drachms in adults, and in children with less than one-third of that quantity. Like chloroform, it may be administered at all periods of life and in all kinds of operations, in the most severe and protracted as well as in the most simple and expeditious.

The mode of administering chloromethyl and the precautions with regard to the patient, as recumbency, emptiness of stomach, and absence of constriction, are the same as in the induction of anæsthesia with chloroform. The fluid may either be poured upon a thickly-folded napkin or it may be placed in an inhaler carefully fitted to the nose, from half a drachm to a drachm being used in the first instance, and a smaller quantity at each repetition until the desired effect is induced, when the anæsthetic influence may readily be maintained with a few drops applied from time to time as long as may be necessary. Air must, of course, be admitted, but not too freely, more especially at first, otherwise it will retard the induction of narcotism. A slight choking condition is often experienced at the beginning of the administration, but this usually passes off rapidly; if not, the inhalation must be momentarily suspended. Any ill effects that may arise must be treated upon the same general principles as in poisoning from chloroform. The agent is more dangerous than chloroform, and it has caused death in a number of instances.

Protoxide of Nitrogen.—This substance, better known as nitrous oxide gas, or laughing gas, was originally employed as an anæsthetic agent by Dr. Beddoes and Sir Humphry Davy, and afterwards by Dr. Horace Wells, of Connecticut, who was the first to administer it successfully for surgical purposes. It is a sweetish, colorless gas, destitute of odor, and is composed of equal parts of nitrogen and oxygen. When perfectly pure, and unmixed with atmospheric air, it is a supporter of vitality and of combustion, and, therefore, entirely safe as an anæsthetic. Its effects are very similar to those of carbonic acid gas, and hence its administration cannot be continued beyond a few minutes without the risk of asphyxia. For this reason it cannot be safely employed in protracted operations. Anæsthesia generally follows in from thirty to sixty seconds, snoring with unconsciousness being usually the first evidence of its induction. The pulse is slightly accelerated, the muscles are relaxed, the lips are livid, the eyes are rolled up, the conjunctiva is insensible, and, if the inhalation be at all protracted, the respiration will be considerably embarrassed and the blood of a dark color, owing to the absence of oxygen. Unless the stomach is loaded with ingesta, there is seldom any vomiting. In the female a good deal of hysterical excitement occasionally occurs. No secondary effects, such as sick headache, mental depression, nausea, or emesis, are liable to arise from its use.

The administration of this gas is effected by means of a gum-elastic inhaler, to which is attached a long tube of similar material, furnished with a mouth-piece, a cylinder of wood, fastened to a string, being previously interposed between the jaws. Recumbency need not be observed, as in the case of chloroform, but it is well to free the body from all constriction. Alarming symptoms are promptly relieved by a supply of fresh air. From six to eight gallons of the fresh gas is the quantity usually required to produce complete anæsthesia. It is proper to add that its effects are weakened by keeping.

Protoxide of nitrogen is more particularly applicable to the minor operations of surgery, as the extraction of teeth, the evacuation of abscesses, the removal of small tumors, and the ligation of hemorrhoids; but it may also be employed in some of the larger operations, as excision of the mammary gland, lithotomy, the perineal section, and the more ordinary amputations. Its great disadvantage is the rapidity with which it loses its anæsthetic effects. It should be given with great caution, if at all, in organic disease of the heart, in pulmonary phthisis, and in congestion of the brain.

Dr. John D. Thomas, of this city, informs me that, up to January, 1882, this gas had been administered by him and his brother, the late Dr. Franklin R. Thomas, since 1865, to 101,500 persons for the extraction of teeth, without one fatal accident. Included in

these cases are two amputations, one of the leg and one of the foot, and operations for sounding for stone in the bladder, anal fistule, clubfoot, and stricture of the urethra. The ages of the patients varied from three to ninety-two. Although some of them labored under organic maladies of the heart and lungs, asthmatic complaints, and various other complications, none experienced any ill effects. Nervous, hysterical women occasionally suffer from temporary depression, which, however, generally readily yields under the use of a glass of sherry or a little brandy and water. Persons in the advanced stages of disease of any important organ, anemic persons, and persons who are liable to frequent attacks of epilepsy, cannot with safety use the gas in this form. The number of deaths from the exhibition of this gas in the hands of different operators probably does not exceed a dozen.

Of all the anæsthetics now before the profession ether is unquestionably the safest, and is the one now universally employed in the hospitals of this country. In private practice, too, it enjoys a decided preference, although there are still many surgeons who use chloroform, believing that, if carefully administered, it is equally free from danger. For many years, I never employed any other article, and even now my confidence in its safety remains unshaken. For some time past, however, I have, in great measure, restricted myself, both in public and private practice, to the use of ether, except in the case of children, in whom I generally prefer chloroform on account of the rapidity of its action and the absence of unpleasant secondary effects. No article that has yet been tried as a means of averting pain is perfectly safe. Anæsthesia is, in almost any event, partial death; and hence no matter what substance may be used for inducing it, the occasional destruction of life must be inevitable.

The danger of the use of chloroform as an anæsthetic may, as a rule, be materially lessened by the administration of a dose of morphia, laudanum, or black drop, within an hour to an hour and a half of the operation. This practice has long been in force in all my more severe clinical cases, and I have the greatest confidence in its efficacy, not only in sustaining the heart's action, which the different preparations of opium are so well known to do, but in preventing the cough, excitement, and muscular rigidity so often witnessed, especially in nervous persons. What is true of chloroform in this respect is still more true of ether, which rarely fails to cause more or less severe and annoying laryngeal and tracheo-bronchial irritation, not unfrequently followed by partial asphyxia due to spasm of the laryngeal muscles. When a full anodyne is given in this way—not, as some have recommended, just before the administration of the ether or chloroform is commenced—I am satisfied from long experience that the agent acts not only more kindly but also much more speedily; that its use may be prolonged with much less danger; and that its after-effects are more promptly recovered from, with less tendency to the nausea and distress in the head so liable to follow, when this practice is neglected, the administration of ether.

At my Clinic at the Jefferson Medical College Hospital where, until recently, I employed chloroform in all my operations, no mishap from its use has ever occurred. Dr. Joseph Hearn, who has been my anæsthetizer for the last eleven years, has given it in many hundred cases, at all periods of life and under almost every variety of disease and accident without any serious occurrence. The fluid, whether chloroform or ether, is always administered gradually, during recumbency, on the empty stomach, with all sources of constriction removed; the respiration and circulation are carefully watched; and a wet towel is always at hand to slap the face the moment any signs of asphyxia appear. In regard to chloroform, my conviction is that there is less risk in the agent itself, provided it is perfectly pure, than there is in the mode of administering it.

It is worthy of remembrance, in regard to the use of anæsthetics, that, as rapid respiration obtunds the morbid sensibility of the respiratory passages, it may often be advantageously employed to prevent the unpleasant primary irritant effects of ether and chloroform inhalation, especially of the former.

For many of the minor operations of surgery, as the opening of boils and abscesses, the ligation of hemorrhoids, and the exploration of the bladder, complete anæsthesia is unnecessary. In such and similar cases, the knife and whatever else may be required, may very properly be employed the moment partial unconsciousness is obtained. Very frequently, indeed, a few whiffs of chloroform are quite sufficient for the purpose, especially in children. I have pursued this method for many years both in private and hospital practice, and its importance has been ably discussed in a paper published upon the subject in 1877 by Dr. John A. Packard, of this city.

Rapid breathing, as a means of preventing pain, was introduced to the notice of the

profession a few years ago by Dr. William G. A. Bonwill, an eminent dentist of this city, and is worthy of more attention than has hitherto been accorded to it. It is, of course, adapted only to minor operations, such as the opening of abscesses, the division of strictures of the urethra, the extraction of teeth, and the explorations of the bladder, vagina, and rectum for the detection and diagnosis of diseases. To produce anything like marked insensibility the number of inspirations should not be less than forty, forty-five, or fifty in the minute, steadily continued for three to five times that period. The best posture is the recumbent, but the sitting posture is not objectionable, provided there are no contraindications. The first effect is generally a feeling of fatigue, with a sense of tingling and of expansion or fullness in different parts of the body. Consciousness is preserved but not always in its full extent; the heart's action is increased in frequency and somewhat weakened; and, when the breathing is carried to an extreme degree, the countenance becomes cyanosed and the patient is seized with dizziness, confusion of ideas, lassitude, and incapability of resistance. These phenomena speedily subside on discontinuing the breathing. In operations it has been noticed that the blood which follows the knife is, when the system is fully impressed, of a venous color. The condition induced by rapid respirations strongly resembles that induced by the inhalation of nitrous oxide gas, and seems, to depend essentially, as Dr. Addinell Hewson, who has paid much attention to the subject, imagines, upon a diminished oxidation and decarbonization of the blood.

This mode of inducing anæsthesia should be practised with a certain degree of care in elderly persons worn out by long-continued suffering, and in persons laboring under organic disease of the heart with a tendency to apoplexy.

Local Anæsthesia.—Various plans have been tried for the purpose of inducing local anæsthesia, but the results have not been such as to hold out much encouragement for their practical application. When we consider the absorbent powers of the skin, it might reasonably be supposed that the endermic use of the more potent anodynes, as opium and its different preparations, aconite, belladonna, hyoscyamus, and kindred articles, might be employed beneficially in this wise, but experience has proved that any effect of this kind that they may possess is exceedingly transient and altogether incapable of serving as a preventive of pain during the application of the knife. The employment of ice, or of the frigorific mixture recommended by Mr. James Arnott, of London, is hardly entitled to more confidence; my experience with it is, it is true, very limited, but I have seen enough of it to satisfy me that its value has been greatly overrated, and that it can never, except, perhaps, in the most trivial cases of injury and disease, be carried to a sufficient extent to prevent pain in surgical operations. In a case in which I tried it during the removal of the mammary gland in an old lady, although the skin and subcutaneous connective tissue were completely congealed, the ice in the latter producing a crackling noise, yet the suffering was most intense, especially during the dissection of the deeper structures, where the effects of the freezing mixture had evidently not penetrated. No one can deny that, in this instance, the remedy had not been carried to a sufficient extent, and yet it certainly exercised but a very feeble influence as an anæsthetic. Besides, the application is not without risk, as the part, if not carefully watched, may be frostbitten, and thus experience unpleasant secondary effects.

Mr. Arnott's freezing mixture consists of two parts of ice and one of common salt, the former being previously reduced to a fine powder in a canvas bag, pounded with a flatiron. The latter should also be pulverized. The two articles are then thoroughly and quickly mixed, either with a knife, or by stirring them together in a gutta-percha or other non-conducting vessel. The mixture is inclosed in thin gauze netting, and as soon as the action of the salt upon the ice is rendered apparent by the dripping of the brine, it is placed upon the part to be benumbed, which is held in a horizontal position during the application. The netting should occasionally be raised to watch and equalize the effect of the remedy. About a quarter of a pound of ice and half that quantity of salt suffice for an ordinary application.

The first effect of the remedy is to chill the part, but this rapidly disappears, and is succeeded by pallor of the surface and a sense of numbness. Very soon the skin is found to be notably shrunken, and to assume a deadly, tallow-like appearance, at the same time that it is rendered somewhat stiff and perfectly insensible. If the application be continued longer, the subcutaneous connective and fatty tissues become partially congealed, as is proved by the fact that they feel hard and crackle slightly under the finger. When the application is properly made, that is, gradually and cautiously, the netting being occasionally raised for the purpose of inspection, it is perfectly harmless and almost unattended with suffering. It is only when it is continued too long that it is likely to be productive

of mischief.   Ordinarily from fifteen minutes to half an hour will be required to secure the desired anæsthetic effect.

Rhigoline, introduced as an anæsthetic, in 1866, by Professor Henry J. Bigelow, produces its specific effects by evaporation, freezing the skin firmly in from five to ten seconds.   Gently applied, the impression is evanescent ; protractedly, it is followed by discoloration of the surface and desquamation of the cuticle.   Rhigoline is particularly serviceable in opening abscesses and felons, in the removal of small tumors, in amputations of the fingers and toes, in phimosis, hemorrhoids, anal fistule, and other minor operations.   The only objection to it is its inflammable character, which prevents it from being conveniently carried about in hot weather.

The method of inducing local anæsthesia with the *ether spray*, devised by Dr. B. W. Richardson, consists in directing upon the part to be operated upon a series of jets of pure rectified ether by means of a small hand-bellows connected with a double tube

Fig. 238.
Richardson's Spray Apparatus.

inserted into a graduated bottle through a perforated cork, as represented in fig. 238. An intense degree of cold may thus be produced, rendering the skin insensible in less than a minute, and the narcotism may, if necessary, be readily extended, after the part has been incised, to any depth that may be desired.   With the aid of a spray catheter, the fluid may be thrown into the nose, rectum, bladder, or uterus.   In operating on the extremities, anæsthesia will be more promptly induced if the current of blood be stopped by compression of the main artery of the limb.   Pure rectified ether thus employed is entirely free from irritating qualities, and possesses the additional advantage of not causing any painful reaction.   It is applicable to the same class of cases as rhigoline.

SPECIAL SURGERY; OR, DISEASES AND INJURIES OF PARTICULAR ORGANS, TEXTURES, AND REGIONS.

CHAPTER I.

DISEASES AND INJURIES OF THE SKIN AND CONNECTIVE TISSUE.

SECT. I.—ERYSIPELAS.

ERYSIPELAS is not only a frequent but a most formidable disease. Produced by various causes, both local and constitutional, it may exist as a primary affection, or occur as a complication of other lesions, modifying their character, interfering with their evolution, and even, at times, entirely supplanting them. Although most common in the skin and connective tissue, it is liable to attack various other structures, particularly the mucous and serous. By dermatologists it is usually ranked among the exanthematous diseases, on account of the discoloration which forms so striking a feature in its symptomatology. The term by which it is generally designated is a Greek one, signifying a tendency to spread.

The most common division of erysipelas is into the simple, phlegmonous, and œdematous. The terms idiopathic and traumatic are also used, according as the disease is dependent upon some constitutional vice, or upon external injury. Attempts have been made to draw a distinction between erysipelas and what has been so graphically described by Dr. Duncan, of Edinburgh, under the name of " Diffuse Inflammation of the Cellular Texture," now more generally known as " cellulitis." No one, however, who has carefully studied the subject, can fail to perceive that the two affections are in reality identical, the only difference between them being that in the one case the morbid action begins in the skin, and in the other in the connective tissue, both structures being always more or less seriously involved during the progress of the disease. The causes, march, symptoms, morbid changes, termination, and mode of treatment are precisely alike in the two cases. Hence I agree perfectly with the late Mr. Thomas Nunneley, of Leeds, who has so critically and ably examined the subject in his excellent Treatise on Erysipelas, published in 1841, that such a distinction is as unnecessary as it is unscientific.

Erysipelas occurs at all periods of life, and in both sexes; but of the two forms of the disease, the idiopathic is most common in women, while the traumatic is most frequently met with in men, simply because the latter are more liable than the former to all kinds of injury and exposure. What influence, if any, temperament exerts upon its production, has not been determined. Nervous, irritable, and intemperate persons are particularly subject to it. The greatest number of cases, at least in this country, occur in the latter part of autumn and early in the spring. Locality, doubtless, exerts an important influence in its causation. Thus, it is well known that it is particularly liable to occur in the narrow, crowded, and filthy streets of large cities, in the confined and ill-ventilated wards of hospitals, and in marshy, malarial districts. The effect of occupation in producing erysipelas has not been ascertained; but there is no question that cooks, blacksmiths, foundry-men, and persons habitually exposed to dry heat, are particularly obnoxious to its attacks.

No region of the body is exempt from its affection, though some are more liable to it than others. The idiopathic form is most frequent in the face, scalp, neck, and trunk, while the traumatic appears to be most common in the extremities, particularly the inferior. The eyelids, nose, and forehead are especially prone to be assailed. Old, de-

crepit subjects, and persons worn out by intemperance and disease, often suffer from erysipelas of the scrotum, vulva, feet, and legs. Injuries of the scalp, tendons, and aponeuroses frequently give rise to the disease, and are liable, in consequence, to be followed in many cases, by the worst results.

Erysipelas occasionally assumes an *epidemic* type. Hippocrates had already observed this fact. During the middle ages a gangrenous erysipelas repeatedly ravaged France, where, from its excessive violence, the disease was called the plague of fire. Erysipelas has frequently prevailed as an endemic in camps, barracks, hospitals, and prisons. In modern times it has been observed in both of these forms in various localities. Dr. Gregory expresses the belief that there is not a single hospital in London which has not occasionally been visited by the endemic variety of the disease. At St. George's Hospital, in that city, he repeatedly saw erysipelas so prevalent that all important surgical operations were obliged to be postponed for fear of the supervention of the malady. The inmates of the old Hôtel-Dieu of Paris were frequently assailed in this way, and the mortality thence arising is said to have been very great. Calmiel states that there are periods when erysipelas prevails so extensively in the lunatic asylums of the French metropolis that the physicians of those institutions are compelled to suspend all treatment by counterirritants, as blisters, setons, issues, and moxas, on account of its great liability to be followed by an outbreak of this affection. Velpeau describes an epidemic erysipelas which prevailed at La Pitié in 1831. In 1844, '5, and '6, the disease was so common in the Louisville Hospital, and also throughout the city of Louisville, where I then resided, that I was obliged, on numerous occasions, to postpone the performance of all operations in which delay was admissible, for fear of giving rise to it. Such was the tendency, at that period, to its occurrence, that the most trivial incision, puncture, or scratch was almost sure to be followed by an attack. For a long time we were obliged, in consequence of this proclivity, to refrain from the use of blisters, leeches, venesection, setons, and issues. Chancroids, buboes, and common ulcers were often invaded in a similar manner. But the epidemic was not confined to that city; it prevailed more or less extensively in different sections of the Union, and carried off an immense number of all classes of people. In many localities there was a marked connection between the affection and puerperal peritonitis, the latter of which proved very fatal.

The epidemic here referred to first showed itself, in 1842, in Canada, whence it rapidly spread to Vermont and New Hampshire. The disease usually began in the throat and fauces, or simultaneously in these parts and upon the cranio-facial region, in the form of a deep red, glossy, œdematous swelling, which gradually extended until it involved the whole of the neighboring structures, the countenance being generally distorted in the most hideous manner, so that the patient could hardly be recognized even by his most intimate acquaintances. The tongue, uvula, and tonsils were enormously swollen, deglutition and breathing were extremely difficult, and death was often produced by suffocation. Delirium and excessive prostration were early and prominent symptoms, and many of the cases perished within the first five days. The disease remained generally confined to the parts originally affected. If the patient survived any length of time, profuse suppuration, and sometimes even extensive sloughing, occurred; abscesses formed in various regions of the body; and, after much suffering, the patient either recovered, or died from exhaustion. In some of the persons whom I attended there was extensive ulceration of the tonsils and arches of the palate, and, in several, complete destruction of the gland of one side. In one case, almost the whole of the occipital bone was stripped of pericranium. Dissection disclosed deep engorgement of the lungs, accompanied, in many cases, by inflammation of the bronchial tubes, and even of the pulmonary parenchyma, and by effusion of serum, or of serum and pus, in the pleura and arachnoid sac. The abdominal and pelvic viscera were generally sound, except in lying-in females, who usually exhibited high evidence of peritonitis, metritis, and phlebitis. In one instance, which occurred quite early in the epidemic, the immediate cause of death was a large metastatic abscess in the left lung, the erysipelas being seated in the corresponding leg.

The disease thus briefly described was generally known in the West under the name of "black tongue," "swelled head," or "erysipelatous fever." It seldom attacked any one under fifteen years, but from that period up it was indiscriminate in its selection of subjects. Females seemed to suffer quite as frequently as men. The poor and the intemperate were its most common victims.

If a *dissection* be made of a limb in an erysipelatous state, it will be found to exhibit various appearances, according to the amount of the diseased action. In the milder grades, there will merely be some degree of induration of the skin, unusual distension of

the vessels, and slight effusion of serum, or of serum and lymph, in the subjacent connective tissue. In the phlegmonous variety, there is generally extensive infiltration of the ordinary inflammatory products; the lymph has a spoiled and unnatural appearance, looking like lard or a mixture of flour and water; abscesses exist in various situations; the connective tissue is converted into grayish or ash-colored sloughs; and the muscles are extensively separated from each other. In a case which I attended in 1846, during the prevalence of epidemic erysipelas, the abscess reached from the hip to the ankle, extensively detaching the muscles from each other and from the bones, which might have been lifted almost bodily from the diseased mass, so completely were they severed from their connections. Pure blood is sometimes extravasated in considerable quantity; and the matter, which varies much in its color and consistence, is often excessively offensive. Metastatic abscesses are occasionally found in the internal viscera, and effusions in the serous cavities. Endocarditis with granular degeneration is not unfrequently observed, and in the more severe and protracted cases, the heart is more or less flabby. Organic disease of the kidneys is often met with, manifesting itself in the lighter forms of nephritis. Evidences of inflammation of the brain and its membranes are occasionally present when the erysipelas occupies the scalp.

The question as to the *contagiousness* of this disease is not fully settled. Much may be said both against and in favor of such a view. My own opinion, founded upon considerable experience, is that the affection, at times, possesses such a character. It is very well known that it is inoculable. Thus, a sponge impregnated with the matter of an erysipelatous sore will very readily communicate the disease to an ulcer or an abraded surface in a sound person, and the same thing is true of poultices, ointments, and other dressings. Facts showing that the nurses and friends of individuals affected with erysipelas often contract the disease are of frequent occurrence. In this way whole families are sometimes cut down. A gentleman, in 1852, lost his only son by this disease. A cousin and a female acquaintance who attended him soon became ill with it, and both died; it then spread to other members of the family, and produced most serious ravages before it was finally arrested. In 1846, when erysipelas reigned as an epidemic in Kentucky, a man was received into the Louisville Hospital with an ulcerated bubo, and about the same time his mistress was also admitted with the prevailing distemper. In consequence of an inability to obtain a female nurse, the man was permitted to attend upon her in that capacity. He soon cohabited with her; in a few days he became excessively ill, the sore in the groin assumed an erysipelatous aspect, and in less than a week from the time of his admission he died from the effects of the malady. In the wards of hospitals erysipelas often spreads from one person to another; and in private practice it is occasionally carried by the physician from one house to another. It is in this manner that the parturient female not unfrequently becomes the victim of the accoucheur.

Causes.—The causes of erysipelas are too numerous and diversified to admit of any very definite specification. As a rule, it may be assumed that whatever has a tendency to disorder the digestive, hepatic, or, in short, any other important function, is capable of producing the disease. So true is this that there is seldom, if ever, a case of the complaint in which such derangement does not play a more or less conspicuous part. The fact is important, as leading to valuable therapeutic considerations. Certain articles of diet either predispose to or induce the malady. Thus, there are some persons who cannot eat shell-fish or some particular kinds of fruit, as strawberries, nuts, and similar substances, without suffering from an attack. The retention of vitiated secretions and undigested food in the alimentary canal often leads to similar results. Derangement of the uterine functions, suppression of the cutaneous perspiration, great mental excitement, the habitual use of ardent spirit, loss of sleep, hard study, inordinate sexual indulgence, and, in short, whatever has a tendency to weaken the corporeal faculties, may be enumerated as so many causes of the disease. A vitiated state of the atmosphere, such as is witnessed in hospitals and other charities, often powerfully predisposes to its attacks, as well as to its continuance. Some of the worst cases of this disease that I have ever seen came on during the progress of albuminuria. Indeed, there is reason to believe that organic disease of the kidney is a not unfrequent cause of erysipelas, especially after violent injuries, severe shock, or great loss of blood.

Erysipelas frequently supervenes upon wounds, both accidental and artificial, interfering with the healing process, and, at times, seriously compromising both the part and the system. The period at which this occurs varies from twenty-four hours to several days, according to the nature and extent of the lesion, the presence or absence of complications, the habits of the patient, the condition of the system, and the state of the atmosphere.

Lacerated, punctured, gunshot, railway, and poisoned wounds are much more liable to be assailed in this manner than incised wounds, although the latter are by no means exempt from it, especially if they involve the scalp, hands, or feet, or if they affect old, intemperate, or debilitated individuals. In a case reported to me by Dr. J. P. Miller, of Kentucky, a severe attack of erysipelas of the eye supervened upon the bite of the common house-fly; and in 1847, in this city, a woman from a similar occurrence lost her life, the wound having been inflicted upon the lip. I have seen destructive erysipelas of a finger produced by a wound inflicted by the fin of a fish, the prick of a needle, and the teeth of man and other animals. Indeed, a punctured wound from any cause is peculiarly prone to take on this kind of action, often followed by the most violent symptoms and the most serious consequences.

When the disease is epidemic, it often shows itself within a very short time after the receipt of an injury, however slight or insignificant. Under such circumstances, indeed, I have, as already stated, known it to follow upon the most trivial wound, scratch, or puncture, as a leech-bite, venesection, vaccination, or the application of a blister. Fractures, dislocations, sprains, contusions, and various other injuries not unfrequently give rise to it. Ulcers, whether common or specific, are often invaded by it, especially when the patients are of a broken constitution. Lying-in females are, in certain conditions of the atmosphere, particularly prone to suffer from erysipelas of the uterus and pelvic veins.

Finally, erysipelas frequently engrafts itself upon other diseases. During the winter of 1857, when the malady was endemic in this city, a number of instances occurred where it supervened upon measles, scarlatina, and typhoid fever. During the epidemic of erysipelas in Louisville, in 1844, '5, '6, every case of disease that was admitted into the public hospital of that city received its peculiar impress, and wore for a time its peculiar livery. When the affection was raging at its fullest height in the institution, many of the patients who were convalescing from other maladies were suddenly seized with diarrhœa, pneumonia, and bronchitis, over which the usual remedies exercised no control, and which generally proved fatal in a few days after the attack.

When erysipelas supervenes upon wounds, its approach is usually denoted by an arrest of the adhesive process, by a tensive, burning sensation in the affected part, by a discharge of thin, sanious matter, or an entire suspension of secretion, and by an œdematous appearance of the surrounding structures. Finally, the characteristic blush occurs, and, gradually diffusing itself, often spreads over a considerable extent of surface.

When erysipelas seizes upon ulcers, as it may at any time, whether they are benign or malignant, simple or specific, the local symptoms closely resemble those which characterize the complaint when it follows upon wounds and contusions. The granulations, if any exist, assume a pale, glossy, unhealthy aspect, the pus is replaced by a thin, ichorous fluid, the part is rendered uncommonly painful, and the edges of the sore, along with the adjacent surface, exhibit a reddish, œdematous appearance. In chancroids and dissection wounds the presence of erysipelas is indicated by reddish, tender lines, formed by the superficial lymphatic vessels, generally extending as high up as the neighboring glands, which, in turn, become swollen and exquisitely painful. The morbid action may, in both cases, be simple or phlegmonous, and is almost always dependent upon derangement of the digestive organs, or the suppression of some habitual discharge.

Erysipelas, consequent upon wounds, contusions, fractures, and dislocations, generally manifests itself within the first forty-eight hours after the receipt of the injury, and often spreads very rapidly over a large extent of surface, as the greater portion of a limb, one side of the trunk, or the whole scalp and face. The accident is particularly liable to supervene upon the more severe forms of these lesions, and is always to be viewed with distrust, as it not unfrequently compromises the patient's recovery. Erysipelas of the scalp, caused by wounds and fractures of the skull, generally appears from the second to the third day, and often proves dangerous by its extension to the brain and its envelops, through the intervascular communications between the pericranium and the dura mater. Such cases always demand the greatest vigilance on the part of the practitioner.

Varieties.—In simple erysipelas, described sometimes as the erythematous form, the disease is confined exclusively to the skin. It manifests itself in a bright, vivid, almost scarlet discoloration of the surface, a pungent, smarting, or burning pain, and a sense of stiffness, with, perhaps, here and there a little vesicle, not larger than the head of a pin, and filled with a serous fluid. The swelling is very slight, and, unless the extent of disease is considerable, there is no particular constitutional disturbance. The attack is usually of short duration, and the subsidence of the local disease is always followed by a furfuraceous desquamation of the epidermis.

Phlegmonous erysipelas is a much more serious lesion than the simple, all the symptoms existing in a higher degree, and the disease often terminating in extensive suppuration, abscess, and even gangrene. The discoloration varies from scarlet to deep purple; there is extensive swelling; vesication soon arises; and the pain is of a violent, burning, tensive, and throbbing character, the part feeling heavy, stiff, numb, and as if it were on fire. The inflammation extends deeply among the different tissues, affecting the skin, connective tissue, muscle, and, in short, everything that comes in its way. As it progresses, suppuration takes place, leading to the formation of extensive abscesses, and the destruction of large portions of the connective and adipose tissues. If the morbid action is very intense, mortification will be apt to arise, its approach being indicated by the development of large blebs, filled with bloody, yellowish, or muddy serum, and by a dark, livid, brownish, or ash-colored appearance of the skin. The constitution sympathizes early and deeply, the symptoms being at first of a sthenic character, but soon becoming typhoid.

The *œdematous* variety depends entirely upon accidental causes, its name being derived from the circumstance of the parts being infiltrated with serosity, and, consequently, pitting under pressure. It is most common in the eyelids, scrotum, prepuce, vulva, and inferior extremities, in persons who are debilitated by previous disease, or who naturally possess a feeble constitution. The swelling is often considerable, but the discoloration and pain are comparatively trivial. The diseased surface has a glossy, distended appearance, and retains the mark of the finger for some time after it has been withdrawn. The inflammation is attended by constitutional disorder, generally of a typhoid character, and is apt to terminate in mortification rather than in abscess, although the latter is often present in the more severe cases.

Erratic erysipelas is characterized, as the name imports, by a disposition to extend from one point to another; it is most commonly met with on the face and forehead, from which it frequently spreads, on the one hand, to the hairy scalp, and, on the other, to the neck and ears. In a case of this form of erysipelas, under my charge, the attack, commencing on the left nates, finally extended over the whole trunk. The disease is generally superficial, and is characterized by an erythematous appearance of the surface, with pungent pain, but little swelling.

Although erysipelas, as previously stated, is generally a disease of the skin, or of the skin and subcutaneous connective tissue, it not unfrequently occurs in other structures, more particularly in the mucous and serous, the joints, the veins, and the absorbent vessels, either as an idiopathic or traumatic affection. Of the mucous membranes the parts most liable to suffer are the tonsils, the palate, the uvula, the pharynx, and the larynx, the disease existing sometimes independently, but more commonly in conjunction with erysipelas of the skin. The affected structures are of a crimson or bright scarlet color, œdematous, incrusted with patches of lymph, exquisitely painful, and attended with great functional disturbance, and high constitutional excitement, rapidly passing into a low, typhoid condition. The breath is excessively fetid, and of a peculiarly contagious character, the attendants not unfrequently becoming inoculated by it.

Erysipelas of the larynx is met with chiefly in the upper portion of the tube, at and immediately below the rima of the glottis, constituting what, since the time of Bayle, has been known as œdema of the windpipe, the parts here being supplied with a considerable quantity of loose connective tissue, whereas lower down the mucous membrane is so firmly adherent as to render distension by inflammatory deposits impossible. The disease, which will receive special attention in the chapter on affections of the air-passages, is particularly dangerous on account of the mechanical impediment which it causes in respiration, as well as the great depression of the vital powers which, usually even at an early stage, attends it. The attack is frequently secondary, or a consequence of an extension of erysipelas from the fauces.

Erysipelas of the serous membranes is most common in the arachnoid and the peritoneum; in the former as a result of injuries of the scalp and cranial bones, and in the latter of the effects of strangulated hernia and contusions of the pelvis and abdomen. Lying-in females not unfrequently suffer from a bad form of erysipelas, the disease sometimes prevailing as an endemic, especially in the crowded wards of hospitals. Attacks of this kind generally begin in the veins of the uterus or in those of the broad ligaments, from which the disease extends to the subserous connective tissue and thence to the peritoneum, the symptoms which follow it being strongly denotive of pyemia, attended with a low, typhoid condition of the system, soon terminating in death. The secretions that are

poured out in this form of erysipelas are commonly aplastic, very copious, highly inoculable, and liable to cause dangerous, if not fatal, dissection wounds in making post-mortem examinations.

Erysipelas of the joints is usually associated with the disease as it occurs in other parts of the body, the most common exciting causes being punctured and gunshot wounds, contusions, and suppression of the cutaneous perspiration. In pyemia the larger joints often suffer more or less severely from this cause, the lining membrane being incrusted with aplastic lymph, and their interior distended with sero-purulent fluid, generally of a highly acrid character.

The veins and lymphatic vessels are often attacked with erysipelas, sometimes primarily, but most frequently secondarily. The most common exciting causes are injuries, as wounds and contusions, surgical operations, as the ligation of varicose veins of the extremities, and violence sustained by the veins of the uterus during parturition. Punctured wounds, more especially of the foot and hand, are very liable to give rise to erysipelas of the absorbent vessels.

Erysipelas sometimes occurs in new-born infants, most commonly in lying-in hospitals, the parts most liable to suffer being the genital organs and the abdomen about the region of the umbilicus. It generally comes on within a few days after birth, and often spreads with frightful rapidity, involving a great extent of surface within a few hours from its first manifestation. Occasionally an instance of congenital erysipelas has been noticed. Want of cleanliness and a vitiated state of the atmosphere are the most common exciting causes of the disease. Inflammation of the umbilical vein is probably occasionally concerned in its production. In the worst forms of infantile erysipelas the affected parts are of a dark red, purple, or livid color, greatly distended, and of extraordinary firmness. A swollen, œdematous condition is sufficiently common when the disease is seated in regions of the body largely supplied with loose connective tissue.

Constitutional Symptoms.—Whatever form it may assume, erysipelas is usually preceded by symptoms denotive of general indisposition, such as a feeling of malaise, or discomfort, creeping, chilly sensations, lassitude, pain in the head and limbs, impaired appetite, and an indisposition to exertion. After continuing in this state for a period varying from twenty-four to thirty-six hours, the disease declares itself in a more open manner. The patient is now suddenly seized with shivering, or violent rigors, followed by, or alternating with, excessive heat, and accompanied by severe cephalalgia, nausea, intense thirst, restlessness, and a great sense of muscular prostration. The tongue is dry and coated, the skin hot, the pulse strong and frequent, the urine high-colored and scanty, and, if the temperature rise to or above 103°, almost invariably albuminous. Systolic murmurs are not uncommon, especially in delapidated or anemic subjects. As the disease progresses, the system becomes more and more exhausted, the mind wanders, and the case soon assumes a typhoid character. Or, typhoid symptoms may be present almost from the very commencement, especially if the patient is old, decrepit, or depressed by previous suffering. In the milder forms of erysipelas, there is often very little, if any, constitutional disturbance.

If blood be drawn during the progress of the disease, it will generally be found to exhibit a sizy appearance. Sometimes it is deeply buffed, and even cupped. What internal or intrinsic changes the mass of blood undergoes in this affection has not been satisfactorily determined. Enough, however, is known to show that in the more severe forms of the affection there is generally a marked increase of fibrin and white corpuscles.

Diagnosis.—Erysipelas is generally so well marked as to render it impossible to confound it with any other disease. The only form which is liable to cause error of diagnosis is the simple, which may be mistaken for erythema, which it certainly very much resembles. The signs of discrimination are, the peculiar character of the pain, which is sharp, pungent, and smarting in erysipelas, and almost absent in erythema; the deeper redness in the former than in the latter, and the tendency also to the evolution of vesicles, which does not exist in erythema.

Pathology.—The pathology of erysipelas is still involved in obscurity. How it is induced, what is its seat, or where it originates, are points concerning which we are wholly ignorant. All that is known is that it has a peculiar predilection for the dermoid and connective tissues, the cellular elements of which, along with the emigrant leucocytes, undergo rapid and enormous proliferation, and that it is usually, if not invariably, associated with disorder of the general system, affecting, probably, both solids and fluids. So

thoroughly am I convinced of the latter fact that I do not believe it would be possible for erysipelas ever to appear in a perfectly sound individual. If this be true, then derangement of the general health, especially as displayed in a vitiated condition of the digestive organs, must be regarded as a most important element in the pathology of this affection, and one which must exert a marked influence upon our curative agents. The opportunities constantly afforded the surgeon, in cases of accidents and operations, of testing this point, peculiarly qualify him for pronouncing upon the question. These remarks do not, of course, apply to epidemic erysipelas, to which every one is more or less liable, but to the ordinary form, the development of which, as is well known, is always so much influenced by intrinsic and extraneous circumstances, as the health and habits of the patient, his residence, the nature of his diet, and the state of his mind. When a person is intemperate, breathes a foul air, eats bad food, or has a troubled mind, the most trivial injury, as the merest prick of the finger, is often followed by a fatal attack of the disease, whereas another, although severely hurt but enjoying better health, may, perhaps, escape entirely, or suffer only in a slight degree. The surgeon, aware of this circumstance, constantly acts upon it in practice, making it a rule never to perform any serious operation until he has put his patient in a proper condition for it by the rectification of his secretions and the improvement of his general health.

Erysipelas has frequently been regarded as consisting essentially in a bad form of capillary phlebitis, it being alleged that the smaller veins are generally found to be involved in the disease, as is shown by the inflamed condition of their coats, and by the existence in their interior of various kinds of substances, as lymph, pus, and coagulated blood. Such changes undoubtedly occur, to a greater or less extent, in all severe cases of the malady ; but they occur, not as a cause, but as a consequence, of the morbid action. Other pathologists, again, consider erysipelas as being essentially an affection of the lymphatics, or of these vessels and of the veins. Finally, there is another class who look upon it as being altogether, from first to last, a blood disease, or, in other words, a species of toxemia. All these views, however, are merely so many conjectures, their truth or falsity not being fully established.

Prognosis.—The prognosis of erysipelas is greatly influenced by the character, extent, and seat of the morbid action, by the age and habits of the patient, and by the absence or presence of complications. Phlegmonous erysipelas is generally more dangerous than the simple or œdematous, as it is more liable to end in extensive suppuration, gangrene, and metastatic abscesses. A simple erysipelas, however, if of great extent, is hardly less dangerous to life than a phlegmonous one, the shock to the nervous system being nearly as severe as in a superficial but extensive burn, which often kills on this account. The disease is particularly to be dreaded when it attacks the scalp, from its liability to extend to the brain. For a similar reason erysipelas of the orbit is often a dangerous affection. Infants, young children, old persons, and the habitually intemperate bear up badly under it. Erysipelas occurring during the progress of other affections, as measles, scarlatina, and typhoid fever, is generally fraught with danger. An epidemic erysipelas is always more destructive than a sporadic one, as it is sure, under such circumstances, to impress itself with peculiar force upon the constitution. Traumatic erysipelas often proves fatal in a surprisingly short time, as in the case of a young butcher, who died under my care in less than three days from a violent attack of this disease of the hand and arm, brought on by a punctured wound inflicted by a hook used for hanging up meat.

Erysipelas occasionally manifests a remarkably relapsing tendency, the disease, after having disappeared from the part originally affected, fastening itself soon after upon some other part. In this way it may linger in the system for weeks or even months, each successive attack being, perhaps, more severe than the preceding one. Such outbreaks are generally characterized by a high degree of temperature.

Treatment.—As erysipelas is developed by such a variety of circumstances, it necessarily demands a corresponding variety of treatment. Experience long ago showed that remedies which afford relief in one case are productive of no benefit in another, and, hence, it is all-important, in every instance, that the curative measures should, if possible, be based upon a correct appreciation of the nature of the exciting causes.

The most important constitutional remedies are bloodletting, emetics, purgatives, diaphoretics, mercurials, anodynes, and stimulants.

General *bloodletting* is rarely necessary ; in fact, in most cases, it proves mischievous, by augmenting the debility of the system, already, perhaps, greatly depressed by the violence of the morbid action. The circumstances which, in my judgment, render a resort to the lancet proper in this complaint are, first, a strong, full, and frequent pulse ;

secondly, a robust and vigorous state of the system; thirdly, excessive pain and tension of the parts; and, lastly, the involvement, threatened or actual, of important internal organs, as the brain, lungs, and throat. The amount of blood to be abstracted must depend upon the effects which the operation exerts upon the system. One moderately copious bleeding, performed early in the disease, will usually be sufficient, and will answer a much better purpose than two or three small ones. Venesection, should, as a rule, be avoided in epidemic erysipelas, and in old, sickly, and intemperate persons. In the epidemic erysipelas which prevailed so extensively thirty-five years ago in various sections of the United States, the abstraction of blood was generally borne very badly, and many lives were lost by its injudicious employment. In the Louisville Hospital not a single patient recovered that was bled for this disease. In erysipelas supervening upon capital operations and severe accidents, as compound fractures and dislocations, wounds, and contusions, proper allowance must be made for the effects of shock, the loss of blood, and the resulting suppurative discharges. Children affected with erysipelas rarely, if ever, require bleeding in any form.

Great contrariety of opinion has prevailed among writers respecting the employment of *emetics* in this disorder, some having pointedly condemned them, while others have expressed themselves most warmly in their favor. In the hands of Desault and his disciples the greatest benefit seems to have attended their exhibition. The probability is that here, as elsewhere, in similar cases, the truth lies between the two extremes; for it can hardly be supposed that a class of remedies of such acknowledged potency in many cutaneous affections should be altogether useless in erysipelas. The cases in which, according to my observation, emetics are mainly indicated are those in which there is marked biliary derangement, along with nausea, loathing of food, headache, pain in the back and limbs, great restlessness, and dryness of the surface. These symptoms, so distressing to the poor sufferer, are often promptly relieved by full emesis, excited by ipecacuanha and tartar emetic, ipecacuanha alone, or salt and mustard, and encouraged by the free use of tepid drinks. In protracted cases, and in the erratic form of the malady, attended with derangement of the digestive organs, gentle emetics often operate like a charm in breaking up the chain of morbid action.

Great stress has always been very justly placed upon the use of *purgatives* in the treatment of erysipelas; and when it is remembered that this disease is often directly dependent upon an overloaded state of the bowels, the presence of irritating ingesta, and the suppression of the secretions of the digestive organs, it is not difficult to discover the reason for the practice. Indeed, it would be hard to find a case in which it would be altogether safe to dispense with them. They are more especially valuable in the earlier stages of the complaint and in strong, robust subjects. In the weak and delicate they must be used with the greatest possible care, lest they induce premature exhaustion. The articles which are mainly relied upon are calomel, rhubarb, and compound extract of colocynth, variously combined, and given in sufficient quantity to produce two or three free and consistent motions. Sometimes the addition of a little tartar emetic or ipecacuanha proves beneficial, especially when there is an arid state of the skin and mouth; while occasionally they may be advantageously replaced by others, as castor oil and spirit of turpentine, castor oil alone, senna, or Rochelle salt. When nausea and headache exist, along with a highly coated tongue, the best cathartic generally is calomel and ipecacuanha, in the proportion of about ten grains of the former to two of the latter, followed, if necessary, in six or eight hours, by a stimulating enema, or some mild laxative. When the bowels have been thoroughly evacuated, none but the most gentle aperients should be employed, as blue mass and rhubarb, Seidlitz powder, or colocynth and hyoscyamus.

Diaphoretics are of the first importance in the treatment of this affection, as there are few cases in which the cutaneous function is not more or less interrupted, perverted, or suspended. After proper depletion, gentle evacuation of the bowels, and the restoration of the secretions of the digestive organs, the administration of medicines calculated to act upon the skin often proves highly serviceable. Among the best of this group of articles are Dover's powder and the salts of antimony and morphia, aided by tepid sponging, or, when the patient's strength admits of it, the warm bath. In children and debilitated persons, the neutral mixture and wine of ipecacuanha may be advantageously resorted to. Aconite, in doses of three drops of the tincture, every two, three, or four hours, generally answers an excellent purpose, especially when there is a hot and arid condition of the surface, with inordinate excitement of the heart. The same is true of veratrum viride.

Anodynes are required to allay pain and induce sleep. When the disease occupies an unusual extent of surface, the system is very much in the condition of that of a person

laboring under a severe burn or scald, and requires, at a very early stage of the complaint, the employment of soothing measures. The remedy, commonly one of the salts of morphia, is administered either by itself, or in union with other articles, especially diaphoretics, in quantities proportioned to the exgencies of the case. As a general rule, the object is best attained by a full dose, repeated twice in the twenty-four hours. To an adult, laboring under great pain and restlessness, provided there is no cephalic trouble, not less than half a grain of morphia should be given at a time. Thus administered, the effects of the remedy are much more decided and beneficial than when it is exhibited in smaller quantities. Delirium, or cerebral disorder, does not necessarily contraindicate the use of anodynes; on the contrary, persons so affected are often greatly benefited by their judicious exhibition. To no class of patients is this remark more applicable than to habitual inebriates, and individuals worn out by previous disease, loss of blood, protracted drainage of the system, or constitutional irritation. Such persons absolutely require at an early period, and in every stage of the malady, the use of anodynes in large doses, in order to prevent exhaustion, and afford time and opportunity for the more efficient action of other remedies. Belladonna, in the form of the extract, is very serviceable in cases of idiopathic erysipelas, and especially the facial variety. When there is much febrile excitement the remedy should be combined with depressants, but when there is much depression it should be administered with quinine.

Mercurials are sometimes useful. They are particularly valuable in the erratic form of erysipelas, and when there is a tendency in the disease to linger in the system, after its principal force has been expended. In such cases they occasionally act like a charm, even when they are not carried to the extent of slight ptyalism, which, however, is often necessary, before the disorder finally relinquishes its grasp. During the epidemic erysipelas which prevailed in Louisville and its vicinity in 1844, '5 and '6, I treated a number of cases upon this plan with the most happy results. Mercury should be most scrupulously avoided in erysipelas attended with a low, typhoid state of the system in old, worn-out subjects, and in persons exhausted by intemperance and dissipation. The best form of exhibition, when the remedy is indicated, is calomel with a small quantity of opium and ipecacuanha, or Dover's powder, to restrain its action on the bowels and allay nervous irritation. In urgent cases two grains of the mineral may be given to an adult every four, six, or eight hours, combined with half a grain of the anodyne. When a less rapid impression is desired, blue mass, iodide of mercury, or the gray powder may be used. In whatever form or manner the remedy be given, its effects should never be carried beyond the limits of the slightest possible ptyalism.

The late Professor John K. Mitchell derived, as he informed me, more benefit in this disease, from the use of *iodide of potassium* than from any other remedy. His plan was, after gentle alvine evacuation, to begin at once with the article, giving it, largely diluted with water, every two or three hours, in doses of five to ten grains, until the attack was arrested, as it usually was in a few days. In the few trials which I have made of this remedy, I have witnessed no material benefit, and in several cases I was obliged to suspend its use at an early period, on account of its nauseating effects.

Stimulants and tonics are imperatively required when there is a tendency to prostration, as indicated by the hard, dry, and brownish tongue, the sordes on the teeth, the small, feeble, and frequent pulse, the twitching of the muscles, the coolness of the surface, and the copious sweats, with more or less delirium. The most reliable articles for this purpose are quinine and iron, in the form of the tincture of the chloride, a scruple of the former being dissolved in an ounce of the latter, and the mixture given in doses of fifteen to thirty drops every two, three, or four hours. When this combination disagrees with the stomach, the articles may be employed separately. In the malarial form of the disease, a not infrequent complication in various sections of the United States, quinine, in large doses, is an indispensable remedy and cannot be administered too soon. It also is particularly reliable when there is a relapsing tendency in the disease, and may then generally be advantageously combined with iron and mercury. The treatment should be aided by the liberal use of brandy, milk punch, wine, ale, or porter, and a generous diet.

Throughout the whole treatment, the greatest attention should be paid to the ventilation and temperature of the patient's apartment; the body and bed clothes should be daily changed, and the cutaneous surface should be frequently sponged with tepid salt water, or some slightly alkaline solution. As disinfectants, free use is made of the chlorides, Labarraque's solution, or permanganate of potassium. As soon as his strength admits of it, the patient should take gentle exercise in the open air, and change his sleeping apartment.

Although *topical remedies* in the treatment of this affection are to be regarded simply

as auxiliary agents, there are few cases in which, if properly employed, they are not of signal service. The list is a very large and varied one, embracing applications of the most opposite character, as warm and cold, dry and moist, astringent and relaxing, stimulating, vesicant, and anodyne.

Leeching is indicated when the patient is young and plethoric, or the disease is in its gravescent stage, and making rapid strides. The fact that the operation is occasionally followed by erysipelas does not, in my judgment, prove that it may not at times be beneficial. It is only in rare cases, and in peculiar conditions of the system, as when the patient is of a very irritable habit, or when the leeches are sickly, that such a result is at all likely to occur. Against such a contingency the judicious practitioner will, of course, always guard. The use of the remedy is particularly indicated in erysipelas of the throat and larynx, the scalp, eyelids, vulva, toes, and fingers. The number of leeches must vary according to circumstances, as the intensity of the morbid action and the vigor of the patient, the flow of blood being always encouraged by warm fomentations until the desired quantity is obtained.

One of the most valuable topical remedies is tincture of iodine, diluted with an equal quantity of alcohol, and laid on by means of a large camel-hair pencil, the end of a stiff feather, or a soft cloth mop, until the surface is of a yellowish, brownish, or mahogany color. The application, which should embrace a small portion of the sound skin, should be repeated at least twice, if not thrice, in the twenty-four hours. In the milder grades of erysipelas a single application occasionally suffices for a cure, while in the more aggravated a long continuance of the remedy may be required. Iodine, employed in the early stage of the disease, generally promptly relieves pain and tension, rapidly promotes the removal of effused fluids, and greatly assists in checking morbid action. Used very freely, it occasionally vesicates, and is thus instrumental in unloading the cutaneous capillaries. Doubtless, it also acts advantageously upon the blood and its vessels, indisposing them to further effusion.

Nitrate of silver, employed either in substance, or in strong solution, as from thirty to sixty grains to the ounce of water, is another very valuable agent in the treatment of this disease. It is applied either directly to the affected surface, or a belt is drawn around it upon the healthy skin, to prevent its further spread. I commonly prefer the former method, using the solid nitrate instead of the solution, so highly recommended by Mr. Higginbottom. In order to apply this substance properly, the surface should previously be divested of all greasy and perspirable matter, otherwise it will not unite with the epidermis, and so prove, in great measure, inert. The part should then be gently moistened with soft water, when the caustic is passed firmly and efficiently over it until the whole has been thoroughly touched. Thus employed, it speedily blackens the epidermis and coagulates its albuminous matter, thereby forming an excellent defence to the delicate tissues beneath. When used more freely it generally vesicates, elevating the cuticle into tolerably large blisters. Mr. Higginbottom applies a strong solution of the nitrate of silver, consisting of three drachms of the salt to the ounce of water, with the addition of a small quantity of nitric acid. I have no experience with the remedy in this form. The probability is that nitrate of silver produces its beneficial effects very much in the same manner as tincture of iodine, changing the tone of the capillary vessels and promoting the absorption of the effused fluids, besides serving as a direct defence to the cutaneous surface by its union with the albuminous matter of the superficial layer of the skin.

The late Dr. Gilbert, of this city, often used pure creasote as a remedy in erysipelas. He applied it lightly once a day to the affected surface with a camel-hair pencil, and found it more effectual in arresting the disease than any other article. Creasote destroys the cuticle, converting it into a whitish substance, which thus defends the inflamed surface from the contact of the air.

Solutions of acetate of lead and opium, Goulard's extract, chloride of ammonium, alcohol, chloride of sodium, carbonate of potassium, sulphate of copper, and quinine, often prove highly beneficial. They are employed of varying strength, and are generally most grateful when used tepid, upon flannel cloths, frequently renewed. In warm weather, and in strong, plethoric subjects, they may be applied cold, but when this is done their effects should be sedulously watched, lest they repel the disease, or throw it upon some internal organ.

Warm water alone, at a temperature of $96°$ to $100°$, is often exceedingly efficacious, especially in erysipelas of the scalp, and in the more ordinary traumatic forms of the disease. It is applied by means of wadding or patent lint, covered with oiled silk, and frequently renewed.

The late Dr. Pitcher, of Detroit, strongly recommended, as an external application, bichloride of mercury, in the proportion of twenty grains of the salt to the ounce of alcohol. During the prevalence of the epidemic, already so frequently alluded to, I had occasion to try this treatment in a number of instances, but I did not find it to possess any advantages whatever over iodine and nitrate of silver. In nearly all the cases, upwards of twenty, the application was promptly followed by vesication and excessive pain, and, in a few, by pretty profuse ptyalism; effects which greatly aggravated the local and constitutional suffering, and rendered a speedy discontinuance of the remedy necessary. Since then I have tried the remedy in a weaker solution, but without any encouraging results.

Velpeau had great confidence in the use of sulphate of iron as a local remedy in erysipelas. The praises, however, which he lavished upon it have not been realized by practitioners generally; and I have myself been entirely disappointed with it. It may be employed in solution, in the proportion of half an ounce to two-thirds of a quart of water; or as an ointment, prepared by mixing one drachm of the impalpable powder with an ounce of lard. The former is applied by means of compresses, frequently moistened; while the latter is rubbed on freely several times in the twenty-four hours.

Dr. Holston has derived marked benefit from the local use of chloroform, brushed over the affected surface for a few minutes with a large camel-hair pencil, the parts being immediately afterwards covered with wadding, and the application repeated, if necessary, at intervals of three to four hours. Prompt relief, it is asserted, usually follows, the disease, even if extensive, often yielding in a very short time.

Bromine has been highly extolled as a local remedy in this disease, more especially by our army surgeons, by whom it was extensively employed during the late war. It is applied directly to the inflamed surface in solution, from twenty to forty drops being mixed with the ounce of water, according to the severity of the morbid action. A small quantity of bromide of potassium may sometimes be advantageously combined with it.

In the milder varieties of erysipelas I have occasionally witnessed excellent results from a liniment of equal parts of laudanum, ammonia, and olive oil, applied upon a soft, thin compress. When the skin is very delicate, the proportion of ammonia may be diminished. The common soap liniment, with the addition of a small quantity of tincture of iodine, and confined with a roller, is also a valuable remedy in simple erysipelas.

Of the various greasy substances that have been recommended in the treatment of this affection, one of the most celebrated is mercurial ointment, first advised in this complaint by Dean and Little, of Pennsylvania. A thick layer of this is spread upon cloth, and secured to the part by means of a bandage, or, what is preferable, rubbed gently but efficiently upon the diseased surface. The article has been highly lauded by Rayer and others, but my own experience has not supplied me with any facts in its favor; indeed, it is doubtful whether it possesses any advantage whatever over common lard, suet, or simple cerate. In infantile erysipelas, I have sometimes derived excellent effects from the application of the ointment of oxide of zinc. Professor Gibson speaks favorably of the use of British oil; and Dr. Coates, of this city, has successfully employed tar ointment. The cranberry poultice has long been a popular remedy in this country, its virtues, as supposed by Dr. Munroe Bond, of New Hampshire, probably depending upon the presence of malic acid.

Dusting the affected surface with starch, flour, arrowroot, prepared chalk, carbonate of zinc, pearl powder, and similar substances, is sometimes useful in the more simple varieties of erysipelas, but entirely unavailing when the disease is deepseated, or of a phlegmonous character. In the former, they occasionally prove beneficial by relieving the disagreeable itching, smarting, or burning sensation of the skin. In superficial erysipelas, I have sometimes obtained advantage from painting the inflamed surface with collodion, the application appearing to impart a healthful stimulus to the cutaneous capillaries, to incite the absorbents, and to contract the skin and subjacent connective tissue.

The treatment of erysipelas by blisters, is peculiarly valuable in the phlegmonous form of the disease, and in erysipelas supervening upon wounds, ulcers, chancroids, buboes, and abrasions. The proper plan is to apply the vesicant directly to the inflamed surface, and to retain it until it has raised the epidermis most thoroughly. The serum is then evacuated with a needle, and the part dressed with a light starch, elm, or linseed poultice.

In children, and in old or sickly persons, the blister must be removed at an early period, otherwise serious mischief may ensue.

The subcutaneous injection of a three per cent. solution of carbolic acid, first suggested by Professor Hueter, on account of the assumed dependence of the disease on the development of parasitic fungi in the tissues, has been abandoned.

When the disease is accompanied by suppuration, great tension, or impending gangrene, nothing short of free incisions or punctures will answer, all other topical remedies being then of a subordinate character, as the object is to afford vent to effused fluids, as serum, lymph, pus, and blood, to relieve capillary strangulation and remove pain and tension. The practice is indicated the moment there is the slightest perceptible fluctuation, and, in violent cases, even as soon as there is considerably throbbing. By thus anticipating the suppurative process, the patient escapes much suffering, as well as loss of texture; for, if the matter is retained in the parts, its inevitable tendency is to burrow among the surrounding structures, and to contaminate the system.

To afford relief, the incisions need not be three, four, or five inches in length, as formerly recommended by Mr. Lawrence and other British surgeons. Such a course is highly cruel and reprehensible; for, independently of the pain which attends the operation, it is liable to be followed by copious hemorrhage, which, occurring at a time when the patient is perhaps ill able to bear it, must often cause serious, if not fatal mischief. A few cuts from half an inch to an inch and a half in length, and deep enough to liberate the pent-up fluids, ought to be sufficient in any case, unless it has been greatly mismanaged, or neglected. In such an event, the incisions may be multiple, being made at suitable distances from each other, and in such a manner as not to interfere with any important structures, as large vessels, nerves, or joints. If hemorrhage be unavoidable, it is to be arrested by the usual means, as compression, styptics, or ligation. The best application after the bleeding has ceased is an emollient poultice, or the warm water-dressing, medicated with acetate of lead and opium. The loss of a small quantity of blood is often of essential benefit in relieving the disease.

Punctures are more particularly useful in the œdematous forms of the disease, to evacuate the serous fluid upon which the distension, which is often a source of so much mischief, mainly depends. When suppuration or gangrene is threatening, punctures must give way to incisions. The number of punctures, and the depth to which they are carried, must vary according to circumstances. The best instrument for making them is a very narrow, sharp-pointed bistoury, introduced perpendicularly to the surface, with the necessary care to avoid important structures.

In the milder forms of erysipelas of the extremities, valuable aid may often be derived from the application of the bandage. It is particularly efficacious in the early stages of the disease, as it tends, if judiciously employed, to support the affected structures, and to prevent vesication and suppuration. The application should be made as equably as possible, and with a certain degree of firmness, its effects being carefully watched, and aided by simple or medicated lotions.

Finally, in the epidemic form of this disease, much may be accomplished by way of prophylaxis. Among the more important elements in this kind of treatment are isolation of the sick, thorough ventilation, personal cleanliness, and an abundance of good, wholesome food. These precautions are particularly necessary in hospitals, prisons, asylums, camps, barracks, and ships. When persons are crowded together, in narrow and confined situations, the air is speedily contaminated, and the disease is sure to spread with fearful rapidity and violence, especially if the body is affected with wounds, contusions, ulcers, or compound fractures. The best internal prophylactic is the tincture of chloride of iron, given in doses of twenty to thirty drops every four or six hours, either alone or in union with quinine, the latter remedy being particularly valuable when the disease is of a malarial character. Arsenic will then also be of great service.

SECT. II.—FURUNCLE OR BOIL.

A furuncle, vulgarly called a boil, is a peculiar inflammation of the skin and connective tissue. Liable to occur upon any portion of the body, excepting, perhaps, the palm of the hand and the sole of the foot, it is most common upon the face, nape of the neck, buttocks, and fingers, often forming in considerable numbers, either simultaneously or successively, although generally there is only one. Both sexes, and all periods of life, are subject to it; the young, however, suffer more frequently than the old or middle-aged. Some persons are habitually affected with boils, being seldom entirely free from them at

any time for years. Now and then they disappear for a while, and then suddenly break out again. Boils are a very common sequel of eruptive affections, as smallpox, measles, scarlatina, and typhoid fever, and, under these circumstances, they occasionally display a marked epidemic tendency. In the latter event, they are very liable to occur in association with carbuncle and whitlow. Children during dentition, and during chronic attacks of cholera, sometimes suffer excessively from this disease. I have often, in these complaints, seen the whole surface literally covered with boils, the patient experiencing great pain and prostration.

The causes of furuncle are generally inappreciable. Occasionally their formation may be traced to external violence, as a contusion, or the concussion sustained by the skin and connective tissue in riding on horseback. In the majority of cases, if not in all, it is obviously connected with a disordered state of the digestive organs, or with some derangement of the secretions. Thus, persons who labor habitually under disease of the liver, and females who are troubled with irregularity or suppression of the menses, are very prone to suffer from its attacks. Diabetes and albuminuria predispose to its occurrence. Large, painful, and obstinate boils not unfrequently follow the application of blisters, especially in young, broken-down children and elderly subjects. Cold water, used endermically for any considerable length of time, as a therapeutic agent, is liable to give rise to similar effects. On the fingers a painful form of boil occasionally has its origin in a hair follicle.

A boil consists essentially in a circumscribed inflammation of the sebaceous and sweat glands and hair follicles, eventuating in suppuration and sloughing. It usually begins as a small, hard, red pimple, which, as it proceeds, gradually assumes a conical figure, the apex being formed by the skin, and the base by the connective tissue, its volume varying from that of a currant to that of a pigeon's egg. The pain which accompanies it is, at first, of a burning, smarting character, but afterwards, especially when matter is about to be formed, it becomes throbbing and exceedingly severe. A sense of tension is also commonly present. The skin is of a dusky, reddish aspect, and exquisitely sensitive to the slightest touch. As the tumor increases, a little vesicle forms at its apex, containing a drop of serum, and indicating the point where the boil will discharge itself. When the furuncle is large, or multiple, there is usually more or less constitutional disturbance, as manifested by the want of appetite, a bad taste in the mouth, headache, chilliness, and a feeling of great uneasiness. Finally, a boil in the lower extremity, or upon the buttock, often gives rise to sympathetic enlargement of the glands of the groin, and in the upper extremity of the glands of the axilla. The period required for the disease to reach its height varies from three to eight days.

If a section be made of a boil, with a view to the examination of its structure, it will be observed to consist of a mass of dead tissue, ordinarily called a core, immersed in thick, yellowish pus, the parts around being very hard, matted together with lymph, and preternaturally vascular. The skin is also indurated, and abnormally tense, red, and injected. Occasionally the contents of the swelling are almost wholly made up of blood, or of a mixture of blood, pus, and slough. This form of boil, to which the term hematoid may be applied, is most common in elderly persons of a broken constitution, and is usually attended with much local and general distress.

It is seldom, under any circumstances, that a furuncle can be made to abort, or to terminate in resolution, its invariable tendency being to suppurate and slough. In its very incipiency, I have occasionally succeeded in arresting its course by a brisk purge, and the application of iodine, but if it has already made some progress, such an attempt will prove altogether futile. The best plan generally is at once to poultice the part, and to make an early and free incision to let out its contents. The relief experienced from the operation is always prompt and decided. The burning, throbbing pain, so constantly present, is always greatly mitigated by the use of a strong solution of carbolic acid in glycerine, applied upon a compress. If the sore is slow in healing, either from the retention of dead connective tissue, or a want of healthy action from other causes, its surface should be well touched with nitrate of silver, the same article, iodine, or a small blister being applied to the surrounding surface. In most cases the patient will be benefited by purgative medicine and light diet.

When there is a decided furuncular diathesis, as when a great number of boils exist simultaneously, or form in rapid succession, benefit may be expected from an occasional emetic, and from mercurial purgatives, with the internal use of iodide of potassium and Donovan's solution. Sometimes Fowler's solution answers a good purpose, or, what I prefer, arsenic in substance, from the tenth to the fifteenth of a grain three times a day.

In very obstinate cases slight ptyalism may be required before the disease finally yields. When boils are developed as a consequence of exhausting diseases, tonics, mineral acids, a nutritious diet, and country air are indicated. Alkalies are useful when there is acidity of the stomach and bowels. Daily bathing with salt water, or water impregnated with bicarbonate of potassium, will occasionally be serviceable, especially when there is unusual torpor of the skin.

SECT. III.—ANTHRAX OR CARBUNCLE.

The most accurate definition that can be given of a carbuncle is that it is a boil on a large scale, with the addition of gangrene, it being, like that affection, a peculiar inflammation of the cutaneous and connective tissues, not circumscribed, however, as in that disorder, but disposed to spread. Its most common seat is the posterior part of the trunk and the nape of the neck, particularly near its junction with the occiput. The gluteal and sacral regions are also liable to the disease, but it is very seldom that it occurs in the extremities. A bad form of carbuncle occasionally forms upon the chin and lower lip.

Elderly persons are most prone to carbuncle, and it is generally believed that such as are fat and indolent, or addicted to the pleasures of the table, are more frequently attacked than the lean and active. In my own practice, however, this has not been the case. On the contrary, the greatest number of instances has occurred in thin subjects, after the age of fifty, whose constitution has been broken down by long-continued intemperance, impoverished diet, deficient clothing, and mental anxiety. In London carbuncle is said to be remarkably common among the lower orders, in consequence of the enormous quantities of ale and porter which they habitually consume. The disease is more frequent in winter than in summer, and in men than in women: occasionally it displays an epidemic tendency. Carbuncle is one of the symptoms of plague. The extent of the inflammation varies from that of a dollar up to that of a large saucer, its average being about that of the palm of a small adult hand.

Of the exciting *causes* of carbuncle nothing satisfactory is known. Most commonly the outbreak of the disease is ascribed to the effects of cold, to disorder of the stomach, overeating, constipation of the bowels, loss of sleep, excessive venery, and other debilitating influences; but how far, or in what degree, these circumstances tend to favor its development it is impossible to say. I have myself long regarded the malady as essentially of a constitutional nature, resembling, in this respect, erysipelas and some other affections; and a careful study of the history of the disease certainly warrants such an interference. A long course of debauch, or indulgence in the pleasures of the table, attended with a vitiated state of the secretions, is, as is well known, highly conductive to the development of carbuncle in its worst forms. When a person has been for years in this condition, eating and drinking luxuriously, and taking hardly any exercise, the slightest exposure to cold, suddenly checking the cutaneous perspiration, would, it may easily be imagined, tend to produce the disease in a part habitually congested and enfeebled in its action. There is then not merely a bad state of the solids, but the blood also comes in for a share in the proceeding, surcharged, as it must be, with irritating materials which the solids have long been unable to throw off as recrementitious substance. Whether, however, this conjecture is correct or not, the fact is indisputable that carbuncle is rarely, if ever, of traumatic origin, or found in persons of a vigorous and healthy circulation. Cases occur in which the disease is evidently connected with, if not directly dependent upon, a diabetic condition of the system.

One of the first *symptoms* of carbuncle is generally an itching, burning, or smarting, with a sense of numbness, in a particular part of the skin, which, on examination, is found to be of a dusky, reddish color, slightly tumid, and somewhat tender on pressure. As the disease progresses, the local distress sensibly increases; the pain soon becomes throbbing and exceedingly violent, the part feeling as if it were in contact with melted lead; the surface assumes a livid hue; the swelling spreads both in circumference and in depth; and the slightest touch of the finger is intolerable. Along with these phenomena, the patient usually experiences a sense of weight and tension, which greatly adds to his suffering. The part is hard, and circumscribed, feeling like the rind of bacon, and occupying a space from the size of a dollar to that of the palm of the hand. Presently vesicles begin to form at the focus of the inflammation, containing a dirty, turbid, yellowish, or sanguinolent fluid, and generally not exceeding the diameter of a pea, although occasionally they are quite large. Upon bursting, these vesicles expose a corresponding number of openings in the true skin, giving the surface a cribriform appearance, and lead-

ing down into the connective tissue, which is already in a state of mortification. The ulcers, for so they may be called, have an irregular, ragged appearance, and are the seat of a foul, irritating discharge, which is often very abundant and exhausting.

Upon dividing the affected structures, the skin is found to be remarkably dense and firm, cutting very much like the rind of bacon. The connective tissue beneath is converted into a slough, having the appearance of a mass of wet tow, bathed with ill-looking matter, and intermixed with flakes of lymph, or matter like putty, thick pus, or curds. When the disease is of unusual extent, there may be considerable involvement of the aponeuroses and muscles, but, in general, these structures are excluded from the morbid action, the skin and subjacent connective tissue alone suffering. At the periphery of the

Incipient Carbuncle.

Ulcerated Carbuncle.

disease the parts are always uncommonly dense, the boundary between it and the healthy structures being established by a deposit of plastic matter, less organizable, however, than in furuncle, the morbid anatomy of which that of a carbuncle so closely resembles. The annexed sketches, figs. 239 and 240, represent this disease in its earlier and more advanced stages.

Important light has recently been thrown upon the peculiar character of some of the morbid processes of carbuncle by the beautiful researches of Dr. J. Collins Warren. In a paper published a few years ago in the Boston Medical and Surgical Journal, he described and delineated what he has called the adipose columns, and has ingeniously pointed out the part they play during the progress of the disease. The columns are particularly well-marked beneath the thick skin on the back and shoulders, where carbuncle is so often met with. The skin here, as well as in some other situations, is perforated, or nearly so, by vertical adipose columns which pass from the fatty structure beneath to the base of each downy hair follicle. Near the base of each column is given off a band of fibrous tissue from the lower borders of the cutis, which extends obliquely downward, and is inserted into the fascia below. These interlacing bands of tissue form a dense recticulum, or network, in which, in this disease, the inflammation takes its rise. As the inflammation is of that variety which rapidly leads to the development of pus, no protective barrier is formed as in abscess, and the result is that purulent infiltration takes place. The dense integument, held firmly down by the tendon-like bands of tissue referred to, yields with difficulty before the accumulating pressure, while the soft structures of the adipose columns offer but slight resistance to the pus globules, which, consequently, find their way rapidly into them, and thence directly upwards to the surface, destroying the hair follicles as they proceed, and forming at the surface a pustule of considerable size. The pus also spreads liberally from the columns into the cutis, working its way through the lymphatic meshes to the papillæ which become enormously distended, and thus give rise to the numberless minute pustules which stud the surface of the carbuncle.

This mode of the formation of pustules is very different from that usually recognized, the ordinary pustules of the skin being described as being situated in the rete mucosum.

In those portions of the skin in which this process of purulent infiltration is rendered excessive, the circulation is arrested and gangrene follows. The honey-combed crater which is thus exposed is formed by the interlacing of bands of tissue, which, tendon-like, have retained their form, if not their vitality.

In purulent infiltrations of the subcutaneous tissue of other portions of the body, the structures are less resisting; the skin is not bound down so firmly, the connective substance is of a delicate nature, and the pus spreads with great facility in a lateral direction. The skin being much thinner the adipose columns are either very short or entirely absent, and the pus finds its way to the surface, if at all, through the ordinary lymph spaces to one of the papillæ, which it distends in the manner already described.

The constitution always, even at an early period of the disease, strongly sympathizes, with the part affected. Hence, fever is generally present soon after its commencement, and sometimes, indeed, almost before there is any marked evidence of the local affection, the first symptom being often a severe rigor, followed by high vascular excitement. However this may be, the case soon assumes an asthenic type, indicative of the depraved condition of the solids and fluids so intimately concerned in the production of the disease. The tongue speedily becomes dry, hard, and brown, sordes collects upon the gums and teeth, the appetite fails, gastric derangement exists, the bowels are constipated, the urine is scanty and high-colored, the skin is hot and arid, the mind is disposed to wander, and the pulse is frequent, soft, and without force. Vomiting is often present to a considerable extent, and the alvine evacuations are generally excessively fetid.

The *diagnosis* of anthrax is sufficiently easy. Its large size, the severity of the attendant pain, and the great constitutional disturbance, will always readily distinguish it from furuncle at its commencement, and afterwards the discrimination will be still further aided by the vesicated and cribriform condition of the skin, so characteristic of carbuncle. The only affection which it at all resembles is a bedsore, but the history of the case, and the situation of the swelling, will always serve as unerring means of distinction. Malignant pustule begins as a little, circumscribed pimple, not as a diffused swelling, as in anthrax, and soon forms a large vesicle, raised above the surrounding level, and resting upon a hard, solid base, which rarely acquires much extent, at least not until the affection has made considerable progress.

The *prognosis* is variable. In general, a carbuncle may be regarded as dangerous when it is multiple, when it is very large, or when it occurs in old, fat subjects, addicted to indolence and over-feeding. The site of the disease also exerts a marked influence upon the issue of the case. Thus, a carbuncle situated on the posterior part of the head and neck will, other things being equal, be more likely to produce death than when it occupies the back, nates, or extremity, inasmuch as it is very liable to involve the brain and arachnoid membrane, causing effusion of serum and lymph. Young and comparatively healthy persons will often recover, although generally not without great suffering, whatever may be the site of the malady. In a case of an immense carbuncle of the nape of the neck, recently under my charge in a stout, fat man, sixty-two years of age, death was occasioned at the end of a fortnight by the supervention of pneumonia and erysipelas.

Treatment.—The treatment of carbuncle must be conducted with special reference to the improvement of the secretions and the support of the system. Few patients will be found to bear bleeding, active purgation, or depletion in any form. It is only when there is extraordinary plethora, combined with great vigor of constitution, that these means should be carried into effect. In all other cases, their inevitable tendency is to do harm, by bringing on premature exhaustion. Efficient purging, however, may be regarded as an indispensable remedy in almost every instance, the object being not only to get rid of irritating fecal matter, but to produce a change in the secretions. For this purpose the medicine should be given early in the disease, and a mercurial cathartic should always be preferred to any other. When marked gastric derangement exists, as indicated by nausea, headache, and pain in the limbs, no time should be lost in administering an efficient emetic, or an emeto-cathartic, as ten grains of calomel and from ten to twenty of ipecacuanha, followed by large draughts of chamomile tea, or infusion of valerian. Clearance having been effected, and function improved or restored, stimulants and tonics will come into play, exhibited warily, especially if cerebral trouble is threatened, yet efficiently if evidence of exhaustion is present, the most suitable articles being quinine, tincture of chloride of iron, and brandy, with nourishing broths. Anodynes will generally be required, in large doses, to allay pain and procure sleep. After the first few days a mild laxative, as blue mass or castor oil, is occasionally given. Determination to the brain must be promptly met by a large blister applied as near as possible to the occiput.

The best topical application, at the commencement of the disease, is the warm water-dressing, strongly medicated with acetate of lead and opium. Pencilling the surface well with tincture of iodine, and then covering it with a mixture of equal parts of olive oil, laudanum, and spirit of turpentine, sometimes produce a very soothing effect. In many cases there is nothing so promptly beneficial as a blister, large enough to include a considerable portion of the healthy skin, and retained until there is thorough vesication : it drains the vessels of serum, allays pain, and makes a salutary impression upon the general system. Leeches are commonly inadmissible, as they occasion severe pain and undue depletion. In the earlier stages of carbuncle, especially in those cases in which the morbid action is spread over a very large surface, speedy and effectual relief may often be afforded by the subcutaneous division of the indurated tissues with a delicate tenotome, introduced at four opposite points, and carried about, under the guidance of the index-finger of the left hand, in such a manner as to traverse the entire swelling. The skin itself is left intact, except at the entrance of the knife. The operation is generally followed by a good deal of bleeding. The pain and tension rapidly subside, the danger of extensive sloughing is effectually obviated, and the vital powers soon begin to rally under the improved condition of the parts. Compression, by means of adhesive strips, applied concentrically from the margin to within a short distance of the centre of the carbuncle, is sometimes highly beneficial, the treatment greatly and rapidly assuaging pain and tension, and materially abridging the cure.

When the disease has passed into gangrene, as evinced by the cribriform and boggy condition of the affected tissues, the great remedy is free incision, the knife being carried, at different points, through the skin down to the healthy structures beneath. The operation at once relieves the horrible pain and tension of the parts, affords nature an opportunity of casting off the sloughs, and puts an effectual barrier to the further extension of the morbid action. Caustics in such a condition are far inferior to the knife, but if the latter is contraindicated, pure carbolic acid, which is the least painful of the escharotics, may be inserted into the openings or injected into the mass with a view of checking the spread of the inflammation and hastening the separation of the sloughs. If the dead tissues are slow in coming away, their extrusion may be expedited with the scissors, the surface of the ulcer being well touched immediately afterwards with dilute acid nitrate of mercury, or solid nitrate of silver, to promote the formation of healthy granulations. The accumulation of matter must be prevented and cleanliness insured by the frequent use of the syringe, charged with weak solutions of chlorinated sodium, carbolic acid, permanganate of potassium, or common salt. As soon as the sore assumes a healthy aspect the parts should be dressed with some mild unguent, as the opiate cerate, elemi ointment, or ointment of the balsam of Peru.

After recovery, the tendency to a recurrence of carbuncle, which is sometimes very strong, should be counteracted by a change of air, attention to diet, a proper regulation of the secretions, and the avoidance of exposure to cold, fatigue, and loss of sleep, conjoined with an alterative course of iodide of potassium, the dose of which should not exceed two grains and a half thrice in the twenty-four hours. If there has been much disorder of the secretions, a very minute quantity of bichloride of mercury may be advantageously conjoined with the potassium. When there is marked derangement of the digestive functions, attended with acidity and flatulence, chlorate of potassium may be given, three times a day, in doses of five to ten grains, until there is manifest improvement in the tone of the stomach and of the general health. A change of air is often indispensable to complete convalescence.

SECT. IV.—GANGRENE AND BEDSORES.

The skin is liable to gangrene, both idiopathic and traumatic, simple and specific, acute and chronic ; but as these several varieties have already received a sufficient share of attention, nothing need be said respecting them here. There is one species, however, which may be briefly described in this place, inasmuch as no special mention has been made of it elsewhere. I allude to what is called *white* gangrene of the skin, an affection the true character of which is still involved in obscurity, nothing that has yet transpired having thrown any light either upon its pathology or treatment.

White gangrene usually comes on without any appreciable cause or premonitory symptoms, in patches of irregular shape, from one to three inches in diameter. The sloughs are of a dead, milky color, and of hard, dryish consistence, yielding little, if any, moisture on pressure. Any portion of the body may be the seat of this affection ; but the arms, back, and chest are the regions most frequently implicated. The disease is ob-

served chiefly in old persons of a broken, anemic constitution. The treatment is conducted with special reference to the improvement of the health by tonics, brandy, and nutritious diet.

Bedsores.—There is another variety of gangrene of the integument which, from the frequency of its occurrence, and the severity of the attendant suffering, merits special attention here. Its immediate cause is steady and protracted pressure, impeding, and generally arresting, the circulation; hence it is exceedingly liable to arise on the sacro-lumbar region, the iliac projections, on the nates, and over the great trochanter, in consequence of long-continued confinement to one particular posture, as in typhoid fever, in severe fractures and wounds, and after surgical operations. It is also very common after violent injury of the spine. I have at this moment under my charge a tall young man, affected for the last six months with paraplegia, who has a large and excessively painful ulcer upon the left buttock, simply from the pressure sustained in sitting on a chair. Occasionally a sore of this kind forms with extraordinary rapidity, leading to the belief that it is due rather to the irritation of the spinal cord or the nerves thence arising than to any direct compression.

The disease is always necessarily preceded by inflammation, but in consequence of the absence of the usual symptoms, the want of proper care in examining these parts and keeping them clean, or the impossibility which the patient experiences in communicating a knowledge of his sufferings, as when he is exhausted by typhoid fever, or other causes, it does not always attract attention until great mischief has been done, eventuating in extensive sloughing, and the establishment of painful, irritable ulcers, which it is often extremely difficult to heal. In some instances the first intimation the patient has of the approaching mortification is a sense of prickling in the affected parts, as if he were lying upon some rough substance, as sawdust or coarse salt. At other times he feels severe pain, of a stinging or biting character, within a few days after he has been exposed to pressure, and which is often so constant and distressing as to deprive him both of appetite and sleep. Upon examining the parts to which the suffering is referred, the surgeon finds that they are red, or marked by an erythematous patch, slightly swollen, with a dense base, congested, and excessively tender on pressure. Ulceration, if it has not already taken place, will be sure to begin in a short time, unless suitable measures are adopted for the patient's relief, and will be speedily followed by mortification, or mortification may take place without being preceded by ulceration.

The extent to which the gangrene may proceed is variable; occasionally it occupies an immense surface, perhaps as large as the crown of a hat, and reaching down to the very bones; at other times it is more limited both in diameter and depth, laying bare merely the muscles, or being even, in great degree, confined to the skin. In rare cases the ravages involve the osseous tissue, and even the coverings of the spinal cord.

Bedsores, unless of very trivial extent, are among the most formidable complications that are liable to arise during the progress of fevers and other diseases, as well as after accidents and operations. As they seldom occur until the vital powers have been materially depressed, the excessive pain and drainage occasioned by them are often so severe as to destroy the patient, or, at all events, greatly retard his convalescence.

The *treatment* of bedsores, or gangrene from pressure, is prophylactic and curative. When there is any probability from the nature of the case that the confinement is likely to be tedious and attended with constant decubitis, or a helpless state of the patient, means should promptly be adopted for hardening those parts of the surface which long experience has taught us as being most liable to suffer under such circumstances. For this purpose they should be brushed once or twice a day with tincture of iodine, at first diluted, and then pure, or washed repeatedly with a saturated solution of alum and tannic acid. The greatest possible attention should be paid to cleanliness, and to the arrangement of the sheets and clothes, that they may not be rolled up under the body, and thus become a source of suffering and disease. As to the use of plasters, I have very little patience with them, for, unless they adhere well, they are extremely liable to become rumpled, much to the detriment of the part and system. Change of posture should receive early attention, although this is not always practicable, from the inability of the patient to maintain himself in any other situation than on the back. When it can be afforded, an air bed should be used, as this is preferable to everything else.

The moment any decided suffering is experienced, or the parts become red and inflamed, a ring-shaped air cushion should be provided for the purpose of equalizing the pressure, or, in the absence of this, an ordinary cushion, with a suitable central hole, the edges being broad and well padded with wool or horsehair. Such a contrivance, however, is a very imperfect substitute for an air or water cushion.

When gangrene is threatened, the best application is tincture of iodine, aided, if there be much pain and tension, by one or two moderately free incisions, and followed by a yeast or port-wine poultice, sprinkled with laudanum, morphia, or powdered opium. Cleanliness is promoted by the liberal use of the chlorides and by the early removal of the sloughs. When granulations begin to spring up, the best dressing will be opiate cerate, a mixture of equal parts of castor oil and balsam of copaiba, or mild mercurial, elemi, balsam of Peru, or blue ointment.

In the more rapid varieties of bedsores, dependent upon spinal irritation from external injury, with paralysis, Dr. Brown-Séquard strongly recommends the application of cold and heat, in the form of pounded ice and hop poultices, frequently alternated, with a view of effecting a salutary change in the circulation of the part. When the sore is indisposed to heal, on account of its inability to form healthy granulations, the most reliable stimulant is the galvanic current, applied in the manner pointed out in the chapter on ulcers.

The constitutional treatment of bedsores must be conducted according to the general rules followed in typhoid states of the system, from whatever cause proceeding. Nutritious food, wine, brandy, milk punch, quinine, iron, and anodynes, are the means chiefly to be relied upon for upholding the flagging powers of nature. This treatment can hardly be commenced too soon whenever there is any tendency to the formation of bedsores, for the very fact that such a disposition exists is a sufficient reason for redoubling our efforts to support the patient's system.

SECT. V.—BURNS AND SCALDS.

There are few accidents which are of more common occurrence than burns and scalds, or which entail a greater amount of suffering and deformity. The progress of civilization, and the improvements in the arts and sciences, have greatly multiplied their frequency and severity, and call for corresponding attention on the part of the surgeon. From what I have seen of these lesions, I am satisfied that few practitioners understand their character, or treat them with the success of which they are capable. One reason, perhaps, of this is that every one has a remedy for them, and that hardly any two agree as to the kind of treatment best adapted to their relief.

Burns and scalds differ from each other simply in this, that the one is the result of dry heat and the other of moist. They both present themselves in various degrees from the slightest erythematous blush of the skin to the total destruction of all the structures of a limb. Their extent is also extremely variable, both as it regards their depth and their superficial area. Thus, while in one case they may involve only a little patch of skin hardly the size of a half-dime, in another they may occupy an immense extent of surface; or, instead of being diffused over a large space, the injury may be concentrated upon a small spot, but penetrate to a considerable depth. These differences are of great practical importance, on account of the influence they exert upon the issue of the case. The division of Dupuytren of burns and scalds, so generally adopted at the present day, seems to me to be most complex and unscientific, and, therefore, well calculated to embarrass the progress of the inquirer. No one can doubt that the more simple the arrangement of a subject is, the more easily, in general, it is understood. In accordance with this idea, I shall describe burns and scalds as consisting of two classes, the simple and complicated, comprehending under the former term those lesions which, however extensive, give rise merely to inflammation, and under the latter those which cause the death of the parts, either on the instant, or within a short time after their infliction.

Burns are most common in winter, among the poorer classes, who are very liable to have their clothes set on fire from the manner in which they crowd around the hearth and grate to keep themselves warm. Women, on account of their peculiar occupations, are more subject to them than men, and children than grown persons. Blacksmiths, plumbers, glassblowers, and foundrymen are particularly exposed in this way. The introduction of gas, camphene, and petroleum has been a fruitful source of these casualties. Scalds, on the other hand, are most common in kitchens, breweries, factories, especially soap and candle, and, in short, in all places where steam is employed, whether for domestic or public purposes. On our western waters, where steamboat explosions are of such frequent occurrence, many persons are annually destroyed by the effects of hot water. Those parts of the body which are habitually exposed, as the hands and face, are most liable to suffer both from burns and scalds, particularly the latter, steam often penetrating the clothes in every direction. Dry and moist flame, hot water, and steam often enter the mouth and throat, producing violent, if not fatal effects. A heated iron has been known to be thrust up the rectum for the purpose of homicide, as in the famous case of Edward II.

Persons with a delicate skin not unfrequently suffer severely from long-continued exposure to the rays of the sun during the heat of summer, as is witnessed among soldiers, carpenters, bricklayers, masons, and farm hands. The affected surface exhibits a red, erythematous appearance, with or without vesication, and the pain is of a burning, itching, or smarting character. As the inflammation recedes, the epidermis drops off in small furfuraceous scales, leaving the surface beneath red and tender.

It is well known that different agents possess different degrees of capacity for caloric, and that, consequently, they are capable of producing different effects when brought in contact with the living tissues. Thus, experience has shown that boiling metal will cause a more severe impression than boiling oil, and boiling oil than boiling water. The intensity of the injury, however, is not always in proportion to the relative capacity of the substance for heat; for it is well ascertained that copper will, other things being equal, occasion a more violent effect than iron, although the latter possesses a greater capacity for caloric. This fact can be explained only on the assumption that some articles are not only better conductors of heat than others, but that they adhere more firmly to the surface, thus favoring its protracted extrication. Alcohol and ether, from their great volatility, usually produce superficial burns; oils, from their more adhesive properties, deep ones.

In the milder forms of these accidents there is merely an erythematous appearance of the skin, such as may readily be produced by exposing the back of the hand for a few moments to a stove, or by applying hot water to it. The discoloration is usually very transient, but at times it is more permanent, lasting for a number of hours, and being, perhaps, soon followed by slight vesication. The pain, of a smarting, pungent character, is comparatively trifling, and soon goes off. The constitution remains unaffected.

The application of heat, whether dry or moist, unless sufficient instantly to destroy the vitality of the part, or so slight as to make only the most superficial and transient impression, is always speedily followed by an evolution of vesicles, containing a thin, watery fluid, identical with the serum of the blood, from which it is derived. When the vesicles are more slow in forming, as when they are the product of the resulting inflammation rather than of the immediate effect of the caloric, their contents are, in general, partly fluid and partly solid, the latter consisting either of lymph or of fibro-albuminous matter. Their volume varies from a pin-head up to that of a fist, their number being usually in an inverse ratio to their dimensions. Cases are occasionally met with where the epidermis nearly of a whole limb, or of the greater portion of the trunk, is elevated into one enormous blister, establishing a most frightful drainage upon the system.

The surface around the vesicles is of a scarlet color, more or less tumefied, and exquisitely tender on pressure, and on exposure to the atmosphere. The pain is of a burning, scalding character, and so severe as to cause the most violent agony. The part rapidly swells, feeling stiff and tense, and the pain assumes a throbbing character. Well-marked constitutional symptoms are always present, especially if the lesion is at all extensive; and the patient may be delirious, excessively restless, and intensely thirsty.

These injuries are said to be complicated when they are attended with the destruction of the vitality of the part, or some other serious lesion, as a wound, fracture, or dislocation. The devitalization may be limited to the skin and subjacent connective tissue, or it may extend much deeper, involving muscle, aponeurosis, vessel, nerve, and bone all in one common eschar. Such accidents are never produced in any other way than by burns, as when a person falls into the fire, or gets his limb in a stove, grate, or furnace. Dreadful scalds, however, sometimes occur from the protracted application of boiling fluids, as happens, now and then, in breweries and soap factories. Under such circumstances, the loss of vitality, although not as extensive as we sometimes find it from the operation of dry caloric, is yet sufficient to be productive of the most terrible ravages. The epidermis comes off in large sheets, no vesicles exist, or only around the border of the injured surface, and the skin is of a dirty grayish, cineritious, or yellowish color, sodden, insensible, and marked, here and there, by a purplish line, indicating the course of a subcutaneous vein.

Besides the pain which invariable attends all burns and scalds, however slight, there is ordinarily more or less constitutional disturbance, coming on at a variable period after the accident; sometimes immediately, at other times not for several hours, days, or weeks. When the injury is at all extensive, all the symptoms of a severe shock will be present. The patient will feel exceedingly cold, or, perhaps, have violent rigors; the pulse will be small, frequent, and feeble; the respiration will be oppressed; and there will be extreme restlessness, along with great thirst and sickness at the stomach. He is, in fact, in great torture, pale, prostrated, agonized. When the shock is excessive, sensibility may be com-

pletely abolished. Reaction taking place, he will have violent fever, a flushed counte-
nance, and a quick, irritable pulse, with a tendency to delirium; pain, of a pungent,
burning character, forming all the while the prominent suffering. If the excitement run
high, there will be danger of overaction in the part, and of inflammation of some of the
internal viscera, the arachnoid membrane, and the mucous lining of the bowel. Numerous
cases have been published within the last twenty-five years going to show that ulceration
of the duodenum is one of the most frequent secondary lesions of scalds and burns; and, in
the more chronic forms of these accidents, the same disease is sometimes widely diffused
over the colon, thus accounting for the profuse and obstinate diarrhœa then so often present.

Albuminuria is a frequent, if indeed not a very common, occurrence in burns and scalds.
A large number of the cases admitted into the Pennsylvania Hospital show, according to
Dr. Morton, evidences of this occurrence. The urine is generally of high specific gravity,
and the quantity of albumen, although variable, is often so considerable as to be declara-
tive of at least more or less congestion of the kidneys. The change makes its appearance,
in violent burns and scalds, soon after reaction takes place, and usually increases in a
marked degree with the rise of temperature. No special clinical significance, certainly
no very serious one, attaches to the presence of albumen, as ordinarily found, in these
lesions. Similar changes, as is well known, not unfrequently occur in the urine after
various other injuries, and after many surgical operations.

Among the more common local consequences of burns and scalds are, the formation of
vicious scars, the adhesion of contiguous surfaces to each other, the retraction of the
affected parts, ankylosis of the joints, and various transformations of the cicatricial struc-
tures, especially the keloid. The scars, which are often of frightful extent, and horribly
disfiguring, possess an extraordinary contractile power, which does not cease for a long
time, which it is almost impossible to counteract, and which frequently draws out of place
every tissue that is brought under its influence, bone not excepted. Owing to this cir-
cumstance, the chin is occasionally drawn down against the sternum, as seen in fig. 241,

Fig. 241.　　　　　　　　　　　　　　　　　　Fig. 242.
Vicious Cicatrices of the Face and Neck.　　　　Contraction of Elbow from Cicatrice of Burn.

and the lower maxilla singularly changed in shape. The fingers may be retracted like
claws, or literally buried in the palm, the hand thrown back at right angle with the wrist,
or the forearm drawn up against the arm, as in fig. 242, from a clinical case, which is
itself, perhaps, firmly pinioned to the side. Similar effects occur in the inferior extremity.
Thus, the foot is sometimes tied to the forepart of the leg, or the leg to the posterior sur-
face of the thigh. In neglected burns of the hand, the fingers are often united to each
other, so as to give them a webbed appearance.

Burns and scalds are among the most dangerous of accidents. If at all extensive they
often terminate fatally from mere shock of the system, without, perhaps, even the slightest
attempt at reaction; or, reaction occurring, life may be assailed by inflammation of some

internal organ; or death may take place at a more remote period, from the secondary effects of the lesion. A superficial injury of this kind is generally dangerous in proportion to its extent. Thus, a scald involving an entire limb, or the greater portion of the trunk, although merely affecting the external layer of the true skin, is always a most serious accident, liable to be followed by the worst results. On the other hand, the danger is hardly less when the lesion is very deep, even if it be not more than a few inches in diameter. When depth and great extent of surface coexsist, the chances are that death will occur without reaction, or soon after the system has rallied from constitutional irritation. Of 125 cases, collected by Erichsen and Holmes, 35 succumbed within the first forty-eight hours. After reaction has taken place, the great danger is from inflammation of the brain, lungs, and intestines, many of the worst cases perishing during the first fortnight. Inflammation of the duodenum, leading, as was originally pointed out by Mr. Curling, to ulceration of its mucous membrane, is an occasional occurrence, coming on, on an average, about the tenth day, the resulting sore, which is generally solitary, and situated just below the pylorus, being of a circular shape, sharp-edged, indolent, and unaccompanied by any characteristic phenomena. Burns and scalds of the chest and abdomen are the most common exciting causes. Death may be produced by hemorrhage, or by peritonitis from perforation of the bowel.

Such injuries are, other things being equal, more dangerous in infants and children than in adults, on account of the greater susceptibility of the nervous system. Old persons, too, are very intolerant of them, and are liable to suffer severely, both primarily and secondarily. Pregnant females occasionally abort from their effects; and in the intemperate they often give rise to delirium tremens and other distressing symptoms. A burn of the neck and scalp is liable to cause arachnitis; of the chest, inflammation of the lung and pleura; of the abdomen, peritonitis and enteritis. Finally, a patient, after having manfully struggled against ebb and tide, as it were, for weeks and months, may finally perish from the effects of profuse discharge, pyemia, erysipelas, or hectic irritation.

Treatment.—The indications in the treatment of these lesions are, first, to produce reaction and calm the system; secondly, to limit the resulting inflammation; thirdly, to promote the sloughing process, when death has taken place, and to favor the development of granulations; fourthly, to moderate contraction, and prevent ankylosis; and, lastly, to sustain the strength during the wasting effects consequent upon the protracted suffering which so often occurs when the patient has escaped from the primary effects of these injuries.

To raise the system from the depression or collapse into which it so frequently sinks, even in comparatively slight burns and scalds, immediate recourse should be had to a full anodyne, along with hot toddy, ammonia, sinapisms to the extremities, and the warm foot-bath, the immersion being cautiously continued from thirty minutes to an hour, according to the exigencies of the case. The quantity of morphia, or whatever form of opium may be used, should be at least double what it is in ordinary accidents, the system being always, under these circumstances, uncommonly tolerant of the medicine. A large dose will not only be conducive to speedy reaction, but will greatly assist in allaying pain and calming the system. If the shock has been unusually severe, it may be necessary, in addition to these means, to use stimulating injections and to rub the spine with some irritating lotion. In the child and the old man, care is taken not to urge on the reaction too rapidly, or to give opium without a certain degree of caution, lest the subsequent excitment should overtax the enfeebled brain and heart, thereby leading to visceral effusion. As the circulation comes up, the stronger stimulants are gradually withdrawn, the more simple alone being now trusted to for relief.

The severe pain consequent upon burns and scalds, is generally promptly relieved, as originally suggested by Dr. F. S. Waters, of Massachusetts, by the use of bicarbonate of sodium, applied in the former case, in the form of a paste made with water, and in the latter, in that of a powder freely sprinkled upon the raw surface.

The second indication is to moderate the resulting inflammation. With this view, various remedies may be employed; but what these remedies ought to be is a point respecting which there is still much contrariety of opinion. In the milder forms of burns and scalds the surgeon can hardly go amiss if he uses almost any of the more common popular articles. He will find that at one time the part and system are most comforted by cold applications, at another by warm; that the one is borne best to-day, the other to-morrow; that one patient is benefited by an ointment, another by a lotion; that in one case he may employ moist applications with most advantage, in another, dry; in short, that the utmost diversity obtains in regard to the tolerance of this remedy or that.

Cold applications are chiefly adapted to very young, robust subjects, during the heat of summer, but even then they should not be employed without the greatest care, on account of their liability to cause internal congestion and effusion. They should be used only so long as they are grateful and soothing to the system, and be discontinued the moment they are found to be disagreeable. They may consist simply of cold water, spirit and water, or weak solutions of acetate of lead; and the same articles may be applied warm, care being taken, when the one class follows the other, that the transition is gradual and gentle, not sudden and violent. If the lesion is very slight, the surface may be covered with poultices of scraped potato, apple, turnip, starch, arrowroot, or slippery elm; carded cotton; saturnine unguents; or cloths wet with liniment made of lime-water and linseed oil. The latter constitutes the famous application so much used at the Carron Iron Works in Scotland; it is, however, exceedingly filthy and disgusting, and should, therefore, be discarded from genteel practice. Carded cotton, an American remedy, has always stood high in the estimation of the public, and there are few articles which are more constantly or more advantageously employed in the treatment of superficial burns and scalds. Tincture of iodine diluted with two parts of alcohol, I have often found of great benefit in the milder varieties of these affections. It is only applicable, however, when the skin is unbroken. The burning, scalding, or smarting sensation, attendant upon this class of injuries, is often promptly relieved by pencilling the affected surface with a weak solution of nitrate of silver, and covering it immediately after with a thick layer of cotton.

In my own practice, I have found nothing so beneficial in the treatment of burns and scalds as carbonate of lead, in the form of white paint, a substance to which, in 1845, I called attention in a short article in Dr. Bell's Bulletin of Medical Science. Numerous observations made since that time by myself and others have only served to confirm the views which I then expressed. The remedy is more particularly applicable to the milder forms of these injuries, but I have also employed it with great advantage in the more severe. If vesicles exist, they must, as a preliminary measure, be evacuated with a fine needle, and the surface well dried, otherwise the lead will not adhere. The lead, mixed with linseed oil to the consistence of thick cream, is then freely applied with a soft brush, the dressing being completed by covering the painted surface with a layer of carded cotton, or old muslin, supported by a moderately firm roller. In the milder cases one such application, retained for several days, generally suffices; whereas in the more severe occasional renewal will be required, depending upon the amount and character of the discharge.

I have never witnessed any bad effects from white lead paint, applied as here directed, although I have used it very freely in numerous cases. In one instance, that of a negro girl, sixteen years of age, who had a most severe and extensive burn of the neck, chest, and abdomen, I continued the remedy for upwards of five weeks, consuming more than a quart of the lead, without observing the slightest injury. In short, my experience induces me to believe that the treatment is perfectly safe in all cases, whatever may be the extent or depth of the lesion, or the age of the patient. When a counterpoison, however, is deemed necessary, it will readily be found in the occasional exhibition of a dose of sulphate of magnesium, which, while it keeps the bowels in a soluble state, combines with the lead, forming an inert sulphate.

White lead paint probably produces its good effects in two ways: first, by forming a varnish to the affected surface, and, secondly, by directly obtunding its nervous sensibility. In many cases it literally acts like a charm, the patient in a few moments becoming perfectly calm, and passing, as it were, from torment to Elysium.

Professor T. G. Richardson, of New Orleans, has obtained excellent effects, in the treatment of burns and scalds, from the use of subnitrate of bismuth and glycerine converted into a thick paint, and freely spread upon the affected surface with a suitable brush, the parts being afterwards covered with carded cotton retained by a roller. In the milder forms of the accident a single application is often sufficient for a cure.

Dr. Addinell Hewson has employed with marked advantage in many cases of burns and scalds, of various grades, what he calls the earth treatment. It consists in covering the raw surface with finely sifted earth, either in the form of dry powder, or of a thick aqueous paste spread upon strips of old, coarse muslin, confined with a roller, and removed as soon as it becomes offensive or saturated with the discharges. In superficial burns and scalds one dressing often suffices for a cure, the parts healing underneath in a few days, the hardened mass coming off in a solid crust. In the more severe cases the application requires occasional renewal, sometimes as often as once every twenty-four hours. Of the efficacy of this plan of treatment I have had sufficient proof to satisfy me of the propriety of its employment. Its beneficial effects seem to be due to two circumstances, the exclusion of

the air from the raw surface, and the specific action of some of the ingredients of the earth, more especially the alumina. One great advantage of this mode of treatment is that the inodular tissue after the completion of the cicatrization is a great deal softer and much more pliant than after the use of any other remedies with which I am acquainted.

In Boston, a plan of treating burns and scalds is used with much advantage, consisting of the application of a thick coating of mucilage of gum arabic, which is immediately after well dusted with the dry powder, the whole forming a complete defence to the raw surface beneath. Mr. Meadows, of London, recommends, for a similar purpose, a mixture of collodion and castor oil, in the proportion of two parts of the former to one of the latter. The preparation, which may be kept ready for use for any length of time in an air-tight bottle, is applied by means of a camel-hair brush, and is speedily converted into a firm, adherent covering, the thickness of which may afterwards be increased if deemed proper. In the more simple forms of scalds and burns, the application of glycerine is occasionally very beneficial; and Dr. John H. Packard, of this city, has derived excellent effects from the use of fresh lard, both in the mild and the more severe varieties of these accidents. Dupuytren's favorite remedy was an aqueous solution of Goulard's extract, retained upon pledgets of old linen; and, with the exception of white lead paint, there is probably no more soothing application.

When a stimulant effect is required, as when the parts are in a condition verging upon gangrene, the most eligible dressing, perhaps, is Kentish's ointment, composed of one ounce of basilicon ointment and one drachm of spirit of turpentine, and spread upon strips of old muslin, bound on lightly with a roller; or, instead of this, the surface may be carefully pencilled with a weak solution of nitrate of silver, nitric acid, or acid nitrate of mercury, and then covered with a yeast, port wine, or tannic acid poultice. Thick soft soap also answers a good purpose, often promptly allaying the smarting consequent upon burns and scalds. When a mere protective is required, finely-powdered charcoal answers an excellent purpose, the surface being thickly sprinkled with it, and renewal effected as soon as the crust becomes saturated with the secretions.

Along with these means, proper attention is paid to the state of the constitution, the bowels are maintained in a soluble condition, diaphoretics are given to restore the functions of the skin, and the diet is carefully adapted to the particular emergencies of the case. The internal organs, especially the brain and lungs, are sedulously watched, any approach of danger from inflammation being promptly counteracted by suitable measures.

If, despite the utmost care and attention, the injury terminates in mortification, or if the parts were devitalized in the first instance, an effort should be made to check its further progress, and to promote the separation of the sloughs, the most eligible remedies being such as are in use for ordinary gangrene. Fetor is corrected with the chlorides. If the sloughs are very firm, they may be detached with the knife, the greatest caution being employed, lest pain and hemorrhage be induced.

As soon as the sloughs have dropped off, the indication is to promote the development of granulations; a circumstance which often requires much judgment and practical skill. One of the best remedies for this purpose is the warm water-dressing, with the addition of two drops of nitric acid to the ounce of fluid. Sometimes the calamine cerate is very soothing, and seems to do good when almost everything else fails. If the granulations manifest a tendency to exuberance, as they are very apt to do, they must be repressed with the scissors, nitrate of silver, and systematic compression, tonics being given to support the system. Cases occur in which these bodies are rendered exquisitely sensitive, the slightest touch being followed by the most lively pain. This condition is generally attended with an irritable state of the constitution, for the relief of which something more than mere topical medication is required. A judicious course of anodynes and tonics, with the occasional application of nitrate of silver, and the constant use of an elm-bark poultice, constitute the proper treatment. Occasionally, no local remedy is so soothing as white lead paint. Whatever means may be employed, it will be found that they will require to be frequently varied, as one loses its effects another taking its place.

In burns from the effects of solar heat, prompt relief is generally afforded by applications of cold water, either simple or medicated with acetate of lead. In the more severe cases the affected surface should be thickly covered with white lead paint.

To obviate deformity constitutes the fourth indication in the treatment of these injuries. The points to be attended to are threefold: first, to prevent adhesion between contiguous surfaces; secondly, to counteract the tendency to vicious contraction; and, thirdly, to guard against ankylosis.

The tendency which the contiguous surfaces have to unite with each other during the

progress of these accidents has already been alluded to. This tendency is not confined to the fingers and toes, but is also exhibited in other parts of the body, as between the arm and trunk, the labia, the thigh and scrotum, the ear and scalp. Wherever it appears, it must be carefully counteracted by the use of the bandage and the interposition of lint, aided, if need be, by splints. It does no credit to a surgeon to send forth his patient, after the completion of cicatrization, with webbed hands and feet, or with his arms pinioned to the side of the chest, although such occurrences are not always entirely avoidable.

The disposition to contraction in burns and scalds attended with loss of substance is always great, and is often productive of the most frightful deformity. To counteract this disposition, recourse should be had, early in the treatment, to carved splints and wire cases, judiciously applied, and steadily used, not only until the parts are well, but for a long time afterwards; experience having shown that the tendency to contraction continues for months, if not for years, after the completion of the cicatrization.

If, from neglect, mismanagement, or unavoidable circumstances, the contraction has seriously impaired the usefulness of the part, or greatly marred good looks, relief should be attempted by the division of the offending cicatrice, or, perhaps, by its excision, the raw edges being afterwards united by suture, or adapted to a flap of the adjacent integument. This operation, constituting what is termed *dermoplasty*, and in connection with which the names of Mütter, Pancoast, and Teale deserve especial commendation, should not, however, be undertaken without due preparation of the system; for it is easy to perceive that, when the cicatrice is very large, two most extensive wounds would have to be made, thus inflicting a violent shock upon the constitution, extremely liable to be followed by erysipelas and a low form of fever, under which the patient might readily sink.

The operation should be performed while the patient is under the influence of an anæsthetic, with the precaution of dissecting out every particle of the inodular tissue. To accomplish this, the surgeon is sometimes obliged to pass deeply among important vessels and nerves, which must, of course, not be interfered with. In conducting such an operation about the neck, care must be taken to prevent the entrance of air into the veins. The bleeding which attends the excision of the cicatrice is generally trifling, and is easily arrested by torsion: when the ligature is unavoidable, it should be composed of raw silk or carbolized catgut, and be left in the wound.

The skin for filling up the gap left by the removal of the inodular tissue should always be taken from the immediate vicinity of the part. Thus, in the neck, it is usually obtained from the shoulder or top of the chest, and, when the wound is very large, two flaps are generally made, one on each side, the object being to guard against sloughing from inadequate nutrition. Due allowance must always be made for shrinkage. Hence the flap should invariably be at least from one-fourth to one-third larger than the wound, have a good, broad pedicle, and be well stitched in its new position, although care must be taken not to place the sutures too near each other, for fear of embarrassing the circulation. The central portions of the flap must be loosely confined with adhesive strips, and the edges covered with charpie, soaked in oil. The wound made by the transplantation of the integument is immediately closed in the usual manner. The parts are kept perfectly at rest, being immovably fixed by suitable apparatus, and the case is afterwards managed according to the general principles of plastic surgery.

Although the results of this operation have been much lauded, my confidence in its ultimate efficacy has been a good deal shaken, experience having shown that, in very many cases, more or less of the deformity for which it was performed will be sure, at no distant day, to recur, the more especially if any portion, however small, of the inodular tissue is left. For this reason few of such procedures can be classed among the triumphs of surgery. It is only when the cicatrice is very soft and superficial that they hold out any prospect of a permanent cure. When the contraction involves the muscles, tendons, fibrous membranes, and bones, forcing them out of their natural shape and position, the art of surgery can be of no avail.

The late Mr. Skey, of London, with a view of obtaining extension of the vicious cicatrice, was in the habit of making numerous minute incisions, extending both through the skin and the subjacent tissues, basing his practice upon the assumption that the contraction of a wound is slight in proportion as the time consumed in the healing process is short. It does not appear, however, that this practice has had any imitators, and I should certainly have no faith in its efficacy or permanent utility.

Skin-grafting will no doubt be found to be of essential service in promoting the cicatrization of burns and scalds, and should be practised as soon as the granulations have assumed a sufficiently healthy appearance to justify the belief that the transplanted skin

will be able to take root and grow. Whether this expedient, however, will prevent the extraordinary tendency to contraction so often witnessed after these lesions, is very questionable. Of several cases which have come to my knowledge, among others one mentioned to me by Dr. J. M. Barton, no permanent benefit resulted.

The joints often become involved during the progress of burns and scalds, either from direct inflammation, or in consequence of the contraction of neighboring muscles, tendons, and aponeuroses. The parts are carefully watched, being moved from time to time, and constantly retained in splints, until all tendency to ankylosis has ceased.

Finally, the secondary constitutional irritation and drainage, so common, and so hazardous in the more severe forms of these accidents, must be met by stimulants, tonics, and anodynes, along with nutritious food, and exercise in the open air. Any diarrhœa that may be present must be checked with opium and astringents, of which acetate of lead and sulphate of zinc deserve particular mention, the former being given in doses of two grains, and the latter in half that quantity, with half a grain of opium, three times in the twenty-four hours. Night-sweats are controlled with atropia, quinine, and elixir of vitriol.

Secondary amputation may be necessary, when, an attempt having been made to save the part, death is likely to occur from the excessive discharge and hectic irritation ; or when the part is found not only to be useless, but to be greatly in the way of the patient's comfort and convenience.

SECT. VI.—FROST-BITE AND CHILBLAIN.

Man possesses in a remarkable degree the faculty of resisting the influence of physical agents. His constitution is able to bear almost any amount of heat and cold, provided the transition from the one to the other is not too great or sudden, and that he himself is at the time in the full enjoyment of his bodily powers. The experiments of Fordyce, Blagden, and others, show what an amount of artificial heat may be endured without entailing any serious effects, and the experience of travellers, as Banks, Solander, Kane, and Hayes, is equally decisive in regard to his capacity of withstanding the effects of low degrees of temperature. It is only, or chiefly, when the alternation from heat to cold is very rapid, or when the application of cold is made in a very concentrated form, upon a part of the body the circulation of which is naturally very languid, that severe consequences are apt to ensue. Baron Larrey, who enjoyed extraordinary opportunities of studying the effects of cold, during Bonaparte's celebrated retreat from Russia, was forcibly struck with the little suffering the soldiers experienced when exposed even for several successive days to the influence of a very low, dry, uniform temperature. Thus, after the battle of Eylau, although the mercury had fallen fifteen degrees below zero of Réaumur's thermometer, none of the French troops complained of frost-bite, notwithstanding many of them had remained in the snow, in an almost inactive state, for upwards of twenty-four hours. Presently, however, a fall of sleet coming on, during which the temperature rose suddenly from eighteen to twenty degrees, immense numbers of those who had been exposed began to suffer from the effects of cold, consisting principally in sharp, pricking pains in the remote parts of the body, especially in the feet, and in a disagreeable sense of numbness and weight. Severe swelling soon followed ; the skin assumed a dusky, reddish appearance ; the joints became stiff and insensible ; feeling and warmth rapidly diminished ; and black spots formed at the roots of the toes and on the back of the foot, announcing the occurrence of gangrene, the extremity looking dry and shrivelled, as in chronic mortification. It was observed that those who had warmed themselves at fires suffered more severely than those who had been more discreet in this respect.

Frost-bite was very prevalent among the English troops during their first winter in the Crimea, and the French suffered in still larger numbers, as well as more severely. The habit which the men had of sleeping in their wet boots, at one time almost universal, contributed greatly to its production, wet and cold combined diminishing the circulation and the vitality of the feet and toes. On the 21st of January, 1855, when, according to Dr. Macleod, the thermometer stood at 5°, not less than 2500 cases of frost-bite were admitted into the French ambulances, and of these 800 died, death in many having no doubt been expedited by the effects of erysipelas, pyemia, and hospital gangrene.

The first effect of dry, cold air is a sense of numbness and weight, with a peculiar prickling or tingling, and an afflux of blood to the surface, giving it a lively reddish appearance. If the impression be maintained for any length of time, the parts become stiff and perfectly insensible ; and the blood, retreating from the surface, leaves it of a pale, whitish aspect, contrasting strikingly with the previous discoloration. When the cold is intense, and suddenly applied, so as speedily to overwhelm the parts, the skin

occasionally is raised into blebs or vesicles and exhibits a mottled appearance, depending upon the presence of coagulated blood in the subcutaneous veins.

The effects of moist cold are very similar to those of dry cold. Upon immersing the hand, for instance, in iced water, there is generally an immediate rush of blood to the surface, and a decided augmentation of its color, soon succeeded by an unpleasant tingling sensation and a marked degree of numbness. By and by, however, the surface becomes white, the skin is elevated into blebs or blisters, exquisite pain arises, and the whole limb notably shrinks. There is thus, in fact, no essential difference in regard to the effects of these two varieties of cold; and the observer cannot fail to perceive how closely the first impressions of both resemble those produced by the application of artificial heat, especially in its dry form.

All parts of the body are liable to suffer from the effects of cold: excepting, however, those rare cases, where the impression has been maintained for an unusual length of time, the toes, feet, heels, fingers, hands, nose, and ears, together with the lips and cheeks, will be found to be more frequently affected than any other structures. Accidents of this description are most common among the poorer classes, those wretched beings whose system is broken down by starvation, intemperance, and every kind of exposure and hardship, tending to depress the vital powers, and to predispose to the development of disease. Sailors and the boatmen on our lakes and rivers are particularly liable to frost-bite.

The primary effects of cold upon the general system are those of an agreeable stimulant: the circulation is increased in force and frequency, a slight glow pervades the surface, and the individual is universally exhilarated. By and by, this agreeable feeling is changed into one of pain and torpor; the brain is oppressed as if under the influence of a powerful narcotic; the whole body is cold and benumbed; and the person, overwhelmed by drowsiness, is obliged to make the most powerful efforts to keep awake. If, in an unlucky moment, he should yield to his inclinations, away from friends and assistants, he sleeps to wake no more; the blood rapidly settles in the internal organs; the nervous fluid ceases to be generated; the respiration becomes heavy and stertorous, and death takes place very much as in ordinary apoplexy. Should the individual, after long and severe exposure, be suddenly brought into a hot room, or placed near a fire, he will run the risk of speedily perishing from asphyxia, brought on by the repulsion of the blood to the brain and lungs; or, should he survive a short time, the frost-bitten parts will be seized with gangrene, the spread of which, as observed by Larrey, is often so rapid and striking as to be perceptible by the eye.

Such are some of the more important local and constitutional effects of cold, when applied in its more severe and protracted forms. As just seen, it may prove destructive both to the part and system; or, reaction taking place, the patient may recover, although he will be likely afterwards to suffer more or less in various parts of the body, especially the feet, ears, nose, and fingers, from the secondary effects of his accidents, which are often as distressing to him as they are perplexing to the practitioner.

Treatment.—The treatment of frost-bite requires no little judgment and adroitness to conduct it to a successful issue. The great indication is to recall the affected parts gradually to their natural condition by restoring circulation and sensibility, in the most gentle and cautious manner, not suddenly, or by severe measures. The first thing to be done is to immerse them in iced water, or to rub them with snow, the friction being made as carefully and lightly as possible, lest overaction be produced, as they are necessarily greatly weakened. If no ice or snow is at hand, the coldest well-water that can be procured must be used; and if the immersion is inconvenient, wet clothes are applied, with the precaution of maintaining the supply of cold and moisture by constant irrigation. Moderate reaction is aimed at and fostered. All warm applications, whether dry or moist, are scrupulously refrained from; the patient must not appproach the fire, immerse his limbs in hot water, or even be in a warm room, otherwise mortification or other disastrous consequences will be certain to follow.

As soon as the natural temperature has been in some degree restored, slightly stimulating lotions will be found serviceable, such as weak solutions of camphor, soap liniment, or tincture of arnica with the addition of a few drops of ammonia to each ounce of fluid. The parts are placed at rest, in an easy and rather elevated position, and lightly covered with a blanket; or, what is better, exposed to the warm air of the apartment, there being now no longer any necessity for keeping the patient in a cool room, as there was in the earlier stages of the treatment. Some mild cordial may now also be given in small quantity, along with a little warm gruel or broth. If the local reaction threaten to be severe, it must be checked by astringent and cooling lotions, attention to position, a

properly regulated diet, and the exhibition of a purgative. For incipient mortification, consequent upon cold, the best remedy is dilute tincture of iodine.

Dr. Hayes, the companion of Dr. Kane in his last Arctic voyage, gives an account of a mode of treatment of frost-bite pursued by the Esquimaux, which deserves brief mention, although it does not differ essentially from that just laid down. A native, says the writer, who had his leg frozen above the knee, to such an extent that it was stiff, colorless, and apparently lifeless, was placed in a snow-house at a temperature of 20° degrees below zero. The parts were now bathed with ice-cold water for about two hours, and then enveloped in furs for about twice that period. At the end of this time frictions were commenced, first with the feathery side of a bird's skin, and then with snow, alternately wrapping the limb in furs, and continuing the rubbing for nearly twenty-four hours. The limb was now carefully covered, and the temperature of the room elevated by lamps above zero. On the third day the man was removed to his own house, and in seventy hours he was able to walk about, with only a slight frost-bite on one of his toes.

When a person has been overpowered by cold, or is nearly frozen to death, the attempts at restoration must be conducted upon the same general principles as when he is suffering merely from the local effects of cold; that is, he should be put in a cool room, and be gently but efficiently rubbed with flannel, wet with brandy, spirit of camphor, or ammoniated liniments, gradually followed by dry frictions and warm covering. If he can swallow, brandy should be given by the mouth, or this or some similar article should be thrown into the rectum; stimulants should be cautiously applied to the nose, especially snuff, and sinapisms to the precordial region, the stomach, and spine. As the circulation and respiration improve, the temperature of the apartment may be gently elevated, and warm broths, or wine whey, or, what is better, warm toddy, administered. The efforts at resuscitation should not be discontinued too soon, since they have occasionally been crowned with success long after all reasonable expectation of recovery had ceased. The practice formerly recommended of immersing the whole body in cold water, in this condition, cannot be too much deprecated, as it could not fail to prove exceedingly injurious.

Pernio or chilblain.—The secondary effects of cold are usually described under the name of pernio or chilblain, and there are several varieties of form in which they may present themselves, as the erythematous, ulcerated, and gangrenous. These effects may supervene upon slight exposure, and hence they are occasionally met with among the better classes of citizens, the parts most liable to suffer being the toes, heel, instep, ears, nose, and fingers. They are usually preceded by a slight vesication, and by burning, tingling sensations, as if the surface had been held near the fire. These effects may soon subside, or they may prove a source of annoyance for many months; in general, however, they are of a transient nature, but the parts, instead of getting completely well, remain weak and congested, and are liable to new attacks of suffering from the slightest causes. Any sudden change in the weather is extremely apt to bring on a paroxysm; the affected structures become red, or of a dusky, purplish hue, swollen, painful, and œdematous; the epidermis is often raised into little blisters, distended with yellowish, turbid, or sanguinolent fluid; and there are few cases in which itching, sometimes almost insupportable, is not a prominent symptom, the patient feeling as if he could tear the parts to pieces.

Ulcers not unfrequently form as an effect of frost-bite. Generally preceded by slight vesication, they are superficial, irritable, and indisposed to heal, the discharge being of a thin, ichorous character; the parts around are red, inflamed, and congested, and the erosive action often spreads over a considerable surface. In some cases it extends very much in depth, and may thus ultimately invade a neighboring joint, bone, tendon, or muscle.

Gangrene is more frequently a primary than a secondary effect of frost-bite; the affected part is of a dark brownish, purplish, or blackish color, cold, insensible, and exquisitely fetid; in some cases the slough is dry and shrivelled, like a rotten pear, in others it is moist and expanded. In persons of weak constitution, and in the more remote parts of the body, where the circulation is naturally very feeble and languid, it often spreads to a considerable extent; but, in general, its tendency is to limit itself to a small space. When considerable, it may invade all the component tissues of a limb, the bones and joints as well as the soft parts.

Pernio may, as already stated, last for many years, alternately disappearing and recurring under the slightest local and constitutional changes. Atmospheric vicissitudes generally exercise a marked influence upon these attacks, the patient being often a complete barometer; a combination of cold and moisture is particularly prejudicial. During the dry weather of summer the disease not unfrequently disappears spontaneously, but is sure to return on the approach of winter. In this manner life may be rendered perfectly

miserable, especially when the chilblain is seated in the feet, the patient being hardly ever able to walk with any degree of comfort or satisfaction.

In the *treatment* of pernio, remedies of a slightly stimulating character are most entitled to confidence. The milder forms of the disease are often speedily relieved by immersion of the part in cold water, followed by the use of a strong solution of acetate of lead and opium, or, what is preferable, dilute tincture of iodine, which, on the whole, I have found to be more beneficial than any other article. Sometimes prompt amelioration is afforded by the application of carded cotton, soap liniment, spirit of camphor, or some other stimulating embrocation.

Any blisters that may form should immediately be opened, and the affected surface freely touched with solid nitrate of silver, or painted with very dilute tincture of iodine. Not unfrequently excellent effects follow the use of weak citrine ointment, or of benzoated zinc ointment. In obstinate cases great advantage often arises from thorough vesication with cantharidal collodion.

The gangrenous form of pernio is treated upon general principles. Fetor is allayed by deodorizers, and sloughs are removed as they become detached. Amputation is refrained from until there is a well-marked line of demarcation, and even then the surgeon should hesitate if the system is not in a healthy condition. Baudens asserts that most operations of this kind, performed in the Crimea, on account of frost-bite, were unsuccessful, owing to the shattered and wasted state of the sick, the great majority of whom had been affected with diarrhœa.

In all cases proper attention must be paid to the general health, the diet being duly regulated, the bowels gently evacuated, and the secretions improved. From neglect of these precautions great temporary suffering is often induced.

SECT. VII.—HYPERTROPHIES OF THE SKIN.

Under hypertrophies of the skin are included two diseases, of which one, dermatolysis, consists of enormous development of the integument as a whole, and the other, elephantiasis, is composed of excessive enlargement of the individual elements of the skin and subcutaneous connective tissue.

1. DERMATOLYSIS.—Dermatolysis, or pachydermatocele, occurs chiefly, if not exclusively, as a congenital affection. It is characterized by a soft, pendulous condition of the skin, which hangs off in loose folds from the surface to which it is naturally attached, as if it had been stuck on without any special object. In all other respects, the integument is apparently perfectly normal, there being not the slightest alteration of color, consistence, or structure, at least so far as we are enabled to judge from inspection. The most common sites of hypertrophy of the skin are the nates, scrotum, prepuce, and vulva. The most remarkable example that I have met with occurred, as a congenital vice, on the back of the neck of a female child, upwards of a year old, the integument forming a large pendulous mass, of a doughy, inelastic feel, extending from ear to ear, and causing unseemly deformity. The child was, in other respects, well formed.

When the hypertrophied integument forms an unsightly mass, or when it proves inconvenient by its bulk, it should be included in an elliptical incision, care being taken not to cut away so much of the skin as to interfere with reunion. If the tumor is very large, and the patient of tender age, the employment of the knife should be postponed until the constitutional stamina are sufficiently developed to enable the child to bear the shock attendant upon so severe an operation. Special pains should be taken to guard against hemorrhage, which might otherwise be profuse.

2. ELEPHANTIASIS.—Arabian elephantiasis, Egyptian sarcocele, tropical bucnemia, spargosis, or the glandular disease of Barbadoes, as it is variously denominated, although uncommon in this country, deserves passing notice, not less on account of the hideous deformity which it induces than its obstinate and intractable character. The favorite seat of this singular disease is the leg, which often acquires an enormous volume and a most grotesque appearance, causing a striking resemblance to the leg of the elephant, whence its name. It is not, however, confined to this part of the body; on the contrary, it is liable to occur in various organs, particularly the scrotum, prepuce, and pudendum, which, in consequence, sometimes acquire an enormous bulk. A tumor of this kind, presented to me by Dr. Bozeman, and removed by him from the genital organs of a negro, weighed forty pounds; and Clot-Bey extirpated one, occupying a similar situation, which weighed one hundred and ten pounds. The adjoining cut, fig. 243, taken from a clinical case, affords a good illustration of elephantiasis of the foot and leg. The enormous bulk

Fig. 243.
Elephantiasis of the Foot and Leg.

which the lower extremity may attain in this disease is well shown in a case reported by Dr. Isaac Smith, of Massachusetts, in which the weight of the limb after amputation exceeded one hundred pounds. Dr. Carnochan has recorded a remarkable example of elephantiasis of the head, face, ears, and neck in a woman of forty-four years of age.

The disease is met with in both sexes, but much oftener in males than in females; it occurs in various races of men, and frequently begins at an early age, although it is most common in young adults. In this country and in Europe the affection is very rare, but in certain parts of Asia, Africa, Syria, Arabia, Egypt, and the West Indies it is extremely prevalent, and sometimes even endemic. It occasionally occurs in several members of the same family; and cases have been recorded in which it was hereditary. In the swampy districts of Bengal, where elephantiasis is exceedingly common, especially in the genital organs, its origin is sometimes apparently due to malarial influences.

Of the intimate nature of elephantiasis nothing satisfactory is known. The disease is evidently of an inflammatory character, but how this is brought about we are entirely ignorant. It has been supposed to be owing to an obstruction of the principal veins of the affected parts, impeding the return of blood, and thus creating congestion and irritation, followed by plastic exudation in the interstices of the cutaneous and connective tissues. From the fact that attacks of erysipelas are not uncommon in the earlier stages of the disease, or, rather, that this affection not unfrequently precedes the outbreak of elephantiasis, it has been imagined that it is essentially dependent upon the disturbance which it occasions in the nutritive and secretory functions of the parts. Others, again, have been led to conclude that the malady essentially consists in an inflammation of the lymphatic vessels, attended with plastic deposits within and around these vessels, and in the lymphatic glands, whereby their caliber is choked up, and, as a necessary consequence, their contents are prevented from discharging themselves into the thoracic duct. This view is, on the whole, extremely plausible, for it really comprises all the cardinal elements of a consistent theory, which the others do not. That there is, in this disease, serious mechanical obstruction of some kind or other, is unquestionable, and I know of none that would be more likely to produce such a result than compression of the lymphatic vessels. If then, it is allowable, in the existing state of the science, to frame a doctrine in respect to the origin of an affection so obscure as elephantiasis is acknowledged to be, we may conclude that it is an inflammation of the absorbents, attended with obstruction of their caliber, and deposits of lymphoid cells, which, becoming gradually organized, are ultimately converted into an analogous fibrous tissue, thereby completely changing the character of the primitive structures, especially the cutaneous and connective.

Dissection shows that the epidermis in this disease is very much thickened, rugose, and so firmly adherent as to come off with difficulty. The cutis is of a whitish color, striated in its texture, and very hard and dense, cutting almost like the rind of bacon. In many cases it is from a quarter of an inch to half an inch in thickness. The papillæ are enormously hypertrophied, and of an elongated shape, forming large bodies which stand off prominently from the substance of the true skin. The connective tissue is completely changed in its character; its areolæ are obliterated, and their place is supplied by a dense, inelastic, fibroid substance, exhibiting none of the properties of the original, interspersed with and occupied by irregular lacunæ filled with lymph or stuffed with desquamated endothelium. In elephantiasis of the leg, the muscles, compressed by the new matter, and deprived of activity, are found to be wasted, pale, and in a state of fatty degeneration. The bloodvessels are generally very much enlarged and thickened, and hence, when an attempt is made to extirpate the morbid mass, as when it occupies the genital organs, tremendous hemorrhage is to be expected. In some cases, however, the larger veins are obliterated, especially in elephantiasis of the lower extremity. The principal nerves have a white, flattened appearance, and are sometimes apparently augmented in size, forming true neuromas. Under the microscope the newly formed tissue—

that upon which the increased volume of the affected parts essentially depends—is found to be uniformly composed of free nuclei, cells, and fibres, in every stage of development, precisely similar to those of a fibroid tumor, properly so called. The development of lymphoid cells, forming thick sheaths around the vessels, is in some instances very striking.

The symptoms are variable. Often, if, indeed, not generally, the disease comes on suddenly and unexpected, without any apparent local or constitutional cause. At times, however, its development is directly traceable to local injury, as a blow, sprain, or contusion; and in quite a number of cases it has seemingly followed upon the protracted immersion of the parts in cold water, the occupation of the individual compelling him to pursue such a habit. The symptoms are at first of an inflammatory type; the affected surface, red and painful, pits on pressure, and imparts a nodulated, cord-like sensation to the finger; the subcutaneous connective tissue is hard and infiltrated; and the movements of the diseased structures soon become stiff, awkward, and embarrassed. Sometimes red lines or streaks extend along the course of the lymphatic vessels, as high up as the nearest glands, which are themselves more or less tender and swollen. Considerable febrile commotion is generally present, but this soon subsides, and the disease gradually lapses into a chronic state, which often ceases only with the patient's life. In the more confirmed cases, fatty degeneration of the other organs occasionally exists.

The diagnosis of elephantiasis is unmistakable, as there is no other affection which bears any resemblance to it. Once seen, it can never be forgotten. The part is not only enlarged; but enormously increased in weight and consistence; it feels heavy and cumbersome, and is as hard, dense, unyielding, and rough as the leg of the animal from the resemblance to which it has derived its name. The surface of the skin, usually much darker than natural, is fissured, grooved, nodulated, or tuberculated, and completely deprived of its normal sensibility. Sores occasionally form upon it, and, gradually spreading in diameter and depth, add greatly to the local distress. Sometimes small, hard, shining scabs exist, not unlike those of ichthyosis. The chronic march of the disease, the remarkable deformity of the affected parts, and the peculiar condition of the skin, will always prevent it from being confounded with anasarca, the only lesion which bears any resemblance to it.

The disease, once fully established, may remain stationary for years, or even during the remainder of life, or it may go on gradually increasing until the affected parts have acquired a volume and a weight many times beyond the natural state. Even under these circumstances, however, the suffering is chiefly of a mechanical character, the general health often continuing good to the last. It is only, in fact, when intractable ulcers form, with an abundant discharge of pus, that the constitution is likely to give way under the local drain and irritation. The prognosis is of course most unfavorable in those countries where the disease is endemic; in Europe and the United States, where it occurs only as a sporadic affection, very few die of it.

There is a form of elephantiasis to which the term nævoid is strictly applicable, as it consists essentially in an enlargement of the affected parts, caused by the presence of a great quantity of dense connective tissue, inlaid with venous structures of a cavernous character, with numerous meshes, not unlike the cavernous structure of the penis, of variable size and shape, some being very fine and delicate, and others equal to the volume of a small marble. The disease is always congenital, and, like ordinary elephantiasis, is generally attended with excessive deformity, its most common site being the lower extremity. The skin is thickened, rugose, very dense, and more or less tuberculated. The tumor can be diminished by pressure, but immediately returns to its former bulk when the pressure is removed. The principal veins and arteries of the part are generally somewhat enlarged.

The *treatment* of elephantiasis is, at best, very unsatisfactory, however early it may be commenced, or however perseveringly and judiciously it may be conducted. Regarding the disease as essentially consisting in inflammation of the lymphatic vessels, or of these vessels and the veins, the most rational plan of treatment that suggests itself is the antiphlogistic, of which leeching, blistering, and the application of tincture of iodine are among the more important and reliable means. The object, in the first instance, should be to reduce local action, in order to prevent subversion of structure. Hence the sooner these remedies are applied, the more likely they will be to effect resolution. As a sorbefacient, no article holds out such strong hopes of relief as tincture of iodine, used either pure or variously diluted to suit the exigencies of each particular case. It not only promotes the removal of effused fluids, but produces a powerful revulsive and antiphlogistic action, and should be employed, steadily and persistently, for many months together. The effects of the treatment will be greatly augmented if the parts be occasionally scarified, to

relieve engorgement, kept at rest in an elevated position, and well bandaged, strapped, or mechanically compressed. Inunction with very dilute ointment of biniodide of mercury also sometimes proves highly beneficial; and, in the earlier stages of the complaint, lotions of acetate of lead, chloride of ammonium, and of rectified spirit, are worthy of trial, especially when there is much pain, with a tendency to rapid effusion and organization. Whatever the local remedies may be, they should invariably be aided by the use of the bandage, renewed twice in the twenty-four hours. I have witnessed good, although not permanent, effects from the earth dressing of Dr. Addinell Hewson.

Constitutional treatment is not to be disregarded. The action of local remedies will be greatly promoted by a restricted diet, by the occasional use of a brisk cathartic, and by the steady influence of saline and antimonial medicines, with a few grains of calomel every night at bedtime, until slight ptyalism is induced. Even general bleeding might be advantageously employed at the beginning of the treatment, in persons of a robust and plethoric state of the system.

When the malady has attained an extraordinary degree of development, or has gone on for many years progressively increasing, or has remained stationary for a long time, no treatment at present known, not even ligation of the principal arteries of the affected tissues, will be likely effectually to eradicate the disease, or, more properly speaking, enable the parts to resume their primitive condition. All topical and general means are, under such circumstances, absolutely unavailing; and the utmost that can reasonably be expected from cutting off the supply of blood to the part is a diminution of its size, not complete restoration of its normal condition. Professor Carnochan deserves great credit for the laudable effort he made, in several cases of elephantiasis of the leg, to arrest the morbid growth, and ultimately cause its absorption, by ligation of the femoral artery; but, although his patients, three in number, were, from all accounts, much benefited, it is questionable whether, in any, a complete cure has been effected. In 1857, I was present at the Philadelphia Hospital, when Dr. Campbell, then surgeon-in-chief, performed an operation of this kind upon a negro, about fifty years of age, who had long been afflicted with this complaint in one of his legs; but the result was not at all encouraging. I saw the man occasionally afterwards for many months, and during my last visit to him, more than a year after the operation, the limb had not undergone any material change, either in volume or consistence. Indeed, such a procedure could hardly be expected to eventuate favorably, when we take into consideration the excessive transformation of the parts and the astonishing enlargement of the branches of the femoral artery. The operation might, if performed early in the disease, and, if conjoined with the use of sorbefacients and the rubber bandage, be worthy of further trial, but its indiscriminate employment is certainly not to be commended. Several cases have been reported by Defour, Vanzetti, and others, in which a cure of this disease is said to have been effected by diminishing the supply of blood in the affected structures by compression of the femoral artery.

Since Dr. Carnochan performed his first operation for the cure of this affection, in 1851, a number of other cases have occurred. Dr. George Fischer, of Hanover, in 1869, published a table of 21 cases, including one of elephantiasis of the neck, face, and ears, of which only 4 were positively known to have terminated successfully. Among the failures were 3 relapses, 2 deaths, and 1 amputation, on account of gangrene of the limb. Dr. Bauer had an instance in which the ligation of the femoral artery was followed by marked relief at the time it was reported, several months after the operation. How far these cases were benefited by the associated treatment, as compression and sorbefacient lotions and unguents, is a point which does not seem to have been well considered. In Dr. Carnochan's patient, a woman forty-four years of age, affected with elephantiasis of the head, face, ears, and neck, only a partial cure was effected by the ligation of both primitive carotid arteries after an interval of six months. In three cases of elephantiasis of the leg treated by ligation of the femoral artery, by Sir J. Fayrer, then of Calcutta, one died of pyemia, and in the other two no permanent benefit accrued from the operation. Dr. McGraw, of Detroit, was unsuccessful in a similar case.

In a man, in whom he had five years previously ligated the femoral artery, Dr. T. G. Morton, of this city, in 1878, excised an inch and a quarter of the sciatic nerve. Six weeks subsequently the leg had diminished in size rather more than one-half, and the skin had resumed its natural appearance. As the patient died of pulmonary phthisis at the expiration of five months, it is impossible to determine whether the operation would have resulted in permanent relief; the limb at the time of death had regained its functions, and the continuity of the nerve was found to be reëstablished.

When the diseased mass is very large, greatly incommoding by its weight and bulk,

and entirely unamenable to treatment, the only resource is removal with the knife.   If it occupy a limb, amputation will be both safe and easy; but if it involve the scrotum, penis, or pudendum, excision may not only be very difficult, but exceedingly perilous, life being endangered, in the first instance, by shock and hemorrhage, and afterwards by erysipelas, pyemia, and exhausting suppuration.   Undue loss of blood may, under such circumstances, occasionally be prevented by elevating and firmly compressing the tumor prior to the operation.   In a case of Arabian elephantiasis in charge of Professor Briggs, of Nashville, in 1875, the limb, removed at the hip-joint, weighed eighty-eight pounds.

The treatment of the nævoid form of the disease must be conducted upon the same general principles as that of ordinary elephantiasis.   The result is usually unsatisfactory.

SECT. VIII.—MORBID GROWTHS.

The skin is liable to a great variety of morbid growths, some of a benign, others of a malignant nature.   The ordinary sebaceous tumor and the molluscous tumor have their seat in the sebaceous follicles.   Lupus is composed of granulation tissue.   The hard and soft fibromas, and keloid are derived from the connective tissue of the cutis, and sarcoma represents embryonic connective tissue.   Of the neoplasms, which are derived from the higher tissues, myoma and neuroma are very uncommon, and angioma is discussed in the chapter on affections of the capillaries.   The epithelial formations include warts, moles, corns, horns, and epithelioma.   Primary scirrhus and encephaloid carcinoma are, so far as I am aware, never met with in the skin.

1. SEBACEOUS TUMORS.

The sebaceous tumor, essentially consisting of an enlargement of a sebaceous gland with the retention of its secretion, has been described under various names, founded either upon the character of its walls, the fancied nature of its contents, or the kind of structure in which it originates, as encysted, atheromatous, meliceric, steatomatous, and follicular. Wen was the familiar appellation by which it was known by the older surgeons.

The manner in which such a tumor is formed is easily explained.   The first link in the morbid chain is the obstruction of a sebaceous gland or cutaneous follicle, either in consequence of adhesive inflammation, or of the inspissated condition of its own secretion, thereby offering a mechanical impediment to its escape.   The matter, thus forcibly retained, gradually increases in quantity, and as it does so it necessarily presses everywhere upon the walls of the gland, which, in time, expands into a strong sac, varying in size from a pea up to a small orange.   A good illustration of this class of morbid growths, as it occurs upon the scalp, is afforded in fig. 244, from a preparation in my private collection.

Fig. 244.

The contents of the sebaceous tumor are extremely variable, both in color and consistence: in general, however, they are thick and whitish, looking and feeling very much like a mass of lard or tallow; occasionally they present the appearance and consistence of honey; and cases are met with in which they bear a very close resemblance to putty, or a thick mixture of flour and water.   Sometimes the contents of a tumor of this kind are thin, watery, or oleaginous, and exceedingly offensive.

The sebaceous tumor is sometimes filled, either partially or completely, with calculous matter, consisting of phosphate and carbonate of lime, cemented together by a minute quantity of animal substance.   A case has

Sebaceous Tumors of the Scalp, one of them being laid open to show its Cyst and Contents.

been recorded in which the integument of the buttocks was completely studded with small collections of this description, evidently seated in the skin follicles.   Similar formations have been observed on the forehead, scalp, nose, shoulders, trunk, and scrotum.

The cyst of the sebaceous tumor is greatly influenced by age, being generally very thin, soft, and delicate in recent cases, and nearly always very thick, tough, and fibrous in old ones; occasionally, indeed, fibrocartilaginous, fibroplastic, or even calcified.   Externally

the cyst is rough, and more or less intimately adherent to the surrounding parts, while internally it is smooth and glistening, not unlike the inner surface of the dura mater. Small sacs are sometimes observed in its interior, and I have occasionally seen indistinct partitions thrown across it, so as to give it a kind of multilocular appearance.

The sebaceous tumor is free from pain, has few vessels, and is generally very tardy in its development, except when the cyst remains for a long time uncommonly thin, when it may be quite rapid. I have never known it to manifest any malignant tendency, although occasionally it inflames, suppurates, and even ulcerates, and becomes the seat of a very fetid discharge. Under these circumstances granulation tissue may spring up from the inner surface of the cyst, and give rise to an irregular fungous mass which simulates malignant disease, as in fig. 245, from Bryant. It originally occupies the substance of the skin, but, as it increases in size, the cyst gradually pushes its way through, so that the connection between them is ultimately completely lost. Meanwhile, the skin itself is remarkably attenuated, and often, in great measure, deprived of hair, especially on the scalp, where, particularly in cases of long standing, the surface is frequently very hard. Here, too, the steady, persistent pressure of such a tumor occasionally indents the skull.

The degree of mobility of the morbid growth is extremely variable, depending upon its age and volume, but, above all, upon the amount and laxity of the connective tissue in the structure in which it is developed. Its shape is almost globular, except when it is subjected to considerable pressure, when it is always more or less compressed or flattened. Its most common sites are the face, forehead, and scalp. It is also met with on the neck, eyelid, shoulder, back, buttock, and scrotum. I have seen two cases of it on the prepuce of small boys who had been circumcised according to the rites of the Jewish Church. It very rarely occurs on the extremities.

Fig. 245.

Fungating Sebaceous Tumor.

The number of sebaceous tumors, although usually small, is extremely variable. Sometimes there is only one, while at other times there may be as many as five or six on the same person. In one instance, in a man forty years of age, I counted upwards of two hundred, mostly upon the head, face and neck, where they nearly all made their appearance when he was quite young, soon after bathing in cold water. They were of the meliceric kind, the contents of many being visible at the enlarged and partially obstructed follicle, where they had concreted into a yellowish, dirty, wax-like substance. They were of a globular or ovoidal shape, and varied in volume from a pea up to that of a hen's egg. Several cases have come under my observation in which two and even three tumors were inclosed in one cyst.

Childhood and adolescence are the periods of life most liable to these formations. I have met with a number of cases in which they existed either before birth, or came on soon after. They occasionally occur in several members of the same family; and now and then they display an evident hereditary tendency, as in a case under my observation, in which the disease existed upon the scalp of a young woman of twenty-seven, and also upon that of her father, a paternal aunt, and her paternal grandmother. The tumors were, respectively, from four to seven in number, and varied in volume from a marble to that of a walnut. Four other instances of a similar character have come under my notice.

The diagnosis of the sebaceous tumor is sufficiently easy. Its chronic march, indolent character, soft, doughy consistence, mobility, and peculiar situation, together with the absence of enlargement of the subcutaneous veins, and the normal appearance of the skin, always serve to distinguish it from other morbid growths.

The only remedy for this variety of tumor is thorough excision, not a particle of the cyst-wall being left, otherwise there will inevitably be repullulation. When the tumor is situated upon the scalp, a single longitudinal incision may be made across it, the flaps being dissected off from each side, and the morbid mass lifted out bodily, without exposing its contents. In fact, simple enucleation is sometimes sufficient. In most other regions, however, the best plan is to lay the tumor open from within outwards, turn out its contents, and then tear away the cyst. If the integument be diseased, the altered structures should be included in an elliptical incision. When a tumor of this kind has been long subjected to pressure, a tedious dissection is sometimes required to effect its removal. However performed, the operation should never be undertaken without due preparation of the system, as I have repeatedly known it to be followed by erysipelas. On one occasion, I removed a small sebaceous tumor from the back part of the head of a young gentle-

man, the case going on well for the first few days; then erysipelas set in, and in a short time this was followed by an immense carbuncle, which came very near proving fatal. The bleeding after such an operation is usually trifling.

2. MOLLUSCOUS TUMORS.

The molluscous tumor, or molluscum sebaceum of the dermatologist, is so called from its fancied resemblance to the knot so often seen upon the bark of the maple tree. When fully developed, it is about the size of a currant, with a central depression, caused by the peculiar arrangement of its contents. Usually of a round, oval, elongated, pedunculated, or wallet-shape, it is of a soft, spongy consistence, of a red, reddish-brown, or dusky yellowish color, and is most commonly met with in adults and elderly subjects, although children are by no means exempt from it. Occurring upon various parts of the body, as the face, neck, back, shoulders, nates, and extremities, it often exists in such immense numbers as to constitute a veritable molluscous diathesis. From the fact that it sometimes affects several members of the same family, it has been supposed by some to be occasionally contagious, or communicable from one person to another by actual contact; an idea which derives countenance from its rapid and consentaneous development in some of these cases. Of its predisposing and its exciting causes nothing is known. The immediate influence under which it is developed is inflammation of the sebaceous glands, leading to a rapid secretion of their peculiar fluid, which, accumulating in their interior, presses their walls asunder, and gives them a lobulated appearance, as is rendered evident on a section of them. Dr. Beale is of opinion that the growth essentially consists in an alteration of the hair follicles and hypertrophy of the dermoid tissues.

The contents of the molluscous tumor are made up mainly of epidermic scales, in union with ovoid, oblong, or cuboid cells, heaped together like a pile of eggs, and occupied either by granular matter, oil globules, or a peculiar homogeneous, undetermined substance.

Left to themselves, molluscous growths are very liable to pass into ulceration, generally beginning at their summits, and gradually progressing until their contents are completely discharged, when the parts usually readily heal. Occasionally they are invaded by gangrene, which may extend so deeply into the subjacent tissues, as to lead, in the event of recovery, to disfiguring scars. Finally, cases occur in which the tumors are atrophied, or transformed into little pendulous wart-like excrescences.

The *treatment* is best conducted with topical stimulants, of which the most efficacious are tincture of iodine, acid nitrate of mercury, sulphate of copper, chloride of zinc, and chromic acid, all more or less diluted, the object being to produce a sorbefacient rather than an escharotic impression. It will generally be found that brushing the surface of the tumor freely once a day with tincture of iodine will not only promptly arrest its development, but rapidly promote its removal. Laying open the morbid growth, and touching the raw surface slightly with solid nitrate of silver, is sometimes very beneficial. The most expeditious method of all, however, more especially if it has a narrow pedicle, is to cut it away with the knife, or to strangulate it with the ligature.

Constitutional treatment is not to be neglected. Occasionally the molluscous tumor disappears, in great degree, if not entirely, simply under the influence of a change of air, a judiciously regulated diet, and attention to the bowels and secretions. When the general health is much disordered, it should be amended by suitable remedies. Cleanliness is of great importance. When there is a scorbutic state of the blood, iron and quinine, with subacid drinks and vegetables, are indicated. Arsenic has sometimes been serviceable in the earlier stages of the disease.

3. LUPUS.

Lupus belongs to the class of granulation tumors, and arises from an independent growth of small cells around the vessels of the cutis. In its earlier stages, the epithelial cells of the sebaceous and sudorific glands proliferate as the result of the irritation to which they are subjected by the accumulation of clusters of germinal cells in their immediate vicinity. Hence Rindfleisch declares that the affection is an adenoma of the sweat and sebaceous glands. As it progresses, however, and the infiltration of the cutis increases, those structures disappear.

Under the term lupus are comprehended two varieties of disease. In the first, which is known as non-exedent lupus, the granulation tissue extends throughout the entire integument, and, undergoing the fibroid transformation, converts the skin into cicatricial tissue. In the second form, or exedent lupus, the small-celled infiltration breaks down,

and the skin and adjacent tissues are destroyed by rapid ulceration. The two affections are, therefore, identical; the only difference being that the non-exedent variety is milder than the other, more tardy in its progress, and not characterized by loss of tissue. The term lupus, signifying wolf, is suggestive of the destructive tendency of the exedent variety.

1. The *non-exedent*, or erythematous, lupus begins as a circumscribed, roundish, swollen, red, or violaceous patch, which is covered by fine grayish or yellowish scales of exfoliating epidermis. The patch slowly spreads over a large extent of surface, and as it increases, the older portions contract, and induce deformity of the features and stiffness in their movements, when it occupies the face, which is its ordinary seat. The altered skin may remain red, and look like a thin cicatrice; or the centre of the diseased area may become polished, of a livid-white color, and dense and hard, feeling like the rind of bacon, and be surrounded by bluish-red nodules or tubercles, of a soft consistence, and covered with epidermic desquamation. These nodules indicate the further extension of the disease.

Erythematous lupus generally comes on without any assignable cause, and soon exhibits its peculiar features. It is commonly supposed that a scrofulous state of the constitution predisposes to its occurrence, and this is probably true, although in a much less degree than has been imagined. My experience certainly does not warrant the conclusion that the origin of the disease has generally any such relation; in most of the cases that have come under my observation, the patients seemed to be peculiarly free from strumous taint, both as it respected the actual state of their own system, and everything like hereditary transmission. Persons of a delicate, ruddy complexion, with light hair, blue eyes, and an unusually active capillary circulation, are most prone to the disease. How far a syphilitic taint of the constitution may act as a predisposing cause of lupus has not been ascertained; unfortunately, it is seldom in the power of the practitioner to obtain a sufficiently accurate account of his cases to enable him to trace, in a satisfactory manner, their various relations.

Although this variety of lupus may occur in any part of the body, it manifests a peculiar predilection for the nose, cheeks, and eyelids, especially the latter. It seldom appears before puberty; and is most common in females after the age of forty. The general health usually remains good; but the altered skin is occasionally the seat of itching or burning pain.

In the treatment of this variety of lupus, none but the mildest and most soothing applications should be employed. The one from which I have derived most benefit is the dilute tincture of iodine, which, while it changes the action of the secernent vessels, promotes the removal of the granulation tissue, and serves as a protective against atmospheric and other injurious impressions. Brushing over the part once every three or four days with a mixture of collodion and glycerine often answers a good purpose; and benefit has also been derived from the application of sapo viridis, tar and mercurial ointment, naphthol, and a mixture of twenty grains of crysophanic acid to the ounce of cosmoline. If under these measures the patch enlarges and its area is limited, it may be scarified, excised, scraped away, or destroyed with the thermo-cautery.

Along with these topical remedies, special attention must be paid to the state of the general health, which is often not a little disordered. The diet should be light, simple, unirritant, and chiefly, if not exclusively, of a vegetable character, the drinks consisting of water, milk, or weak tea; the bowels and secretions should be regulated with blue mass and ipecacuanha, or blue mass and colocynth; and, if signs of debility exist, tonics should be resorted to, in combination with alterants, of which the best are quinine and iodide of iron, with a minute quantity of bichloride of mercury and arsenious acid. Of late, very favorable mention has been made of the use of the chloride of arsenic in the treatment of this affection, in doses varying from eight to fifteen drops thrice a day, and a number of cases illustrative of its beneficial effects have been reported. Of its efficacy, however, I can say nothing from personal experience. When the vital forces are much impaired, cod-liver oil and milk punch must be pressed into the service.

2. The *exedent* lupus, often described as the serpiginous ulcer of the face, generally begins either as small, hard, white, shining tubercles, or as a fissure, crack, or excoriation, with indurated edges, and a thin, brownish incrustation. In either case, it soon exhibits its characteristic tendency to spread, not in depth, but circumferentially, for it rarely, at least in its earlier stages, penetrates beyond the substance of the true skin, or even far into that. In fact, it is essentially a superficial ulcer, passing generally from one point to another, but seldom involving the deeper structures, except, perhaps, when it appears on the ala of the nose, where it occasionally evinces a highly erosive disposition. When it effects the eyelids, it may, in time, extend to the fibres of the orbicular muscle, and

even to the tarsal cartilage, but, in general, it remains limited for years to the skin, or skin and connective tissue. The parts around the ulcer are hard, puckered, tender, and usually somewhat reddish, although very often they retain their normal color. The ulcer is the seat of occasional, darting, stinging, or shooting pain, and of more or less itching, generally much more disagreeable than the pain itself. When the crust, which is usually very thin, and of a brownish or blackish color, drops off, it is speedily succeeded by another of a similar kind. When the surface is thus exposed, it is occasionally found to be covered by very red, sensitive granulations, smeared over with thick, yellowish, viscid pus, and disposed to bleed on the slightest touch. The edges of the ulcer are usually steep, jagged, and slightly everted. As the sore spreads in one direction, it often heals in another, leaving a yellowish, hard, and shrivelled scar, strikingly contrasting with the surrounding parts.

The exedent variety of lupus is most common before puberty, a feature which, when considered in connection with its liability to coexist in several regions of the body, and the absence of hard, everted edges, serves to distinguish it from epithelioma. The probability is that writers often confound this affection with the effects of a syphilitic taint of the system, exhibiting itself in the form of one or more superficial, foul, obstinate ulcers, which, when the diagnosis is properly understood, always promptly disappear under the use of iodide of potassium and bichloride of mercury.

In the treatment of exedent lupus the same general remedies are indicated as in the erythematous variety. Of local measures the caustic agents are always required to arrest the progress of the disease and to set up a healthy action. Of late years I have been in in the habit of scraping away the diseased tissues, and immediately applying to the raw surface either the ethylate of sodium or Esmarch's powder, which is composed of one part each of arsenious acid and muriate of morphia, eight parts of calomel, and forty-eight parts of powdered gum arabic. When the eschar drops off, cicatrization is promoted by a slippery-elm poultice or water dressing.

4. FIBROUS TUMORS.

1. *Hard fibromas.*—Circumscribed fibromas, composed of compact fibrillar connective tissue, are occasionally met with in the cutis, especially in young adults; they usually come on without any assignable cause, are always very tardy in their development, and are free from malignancy. The most common site of circumscribed hard fibromas of the skin are the neck, chest, and shoulder, but they may occur at all points of the body, even upon the fingers and toes. Varying in size in different cases, they seldom exceed, when attention is first called to them, the volume of a hazlenut or an almond; they are of a firm consistence, dense, and inelastic, creaking under the knife, and exhibiting, when divided, a homogeneous appearance not unlike that of an unripe pear or turnip, with but little evidence of vascularity. Their surface is generally smooth, or slightly fissured, pervaded by small straggling vessels, and somewhat lighter than that of the skin in the substance of which they are developed. Movable at first, they manifest a disposition, as they increase in bulk, to extend into the subcutaneous connective tissue, to contract adhesions, and to become affected with sharp, darting pains, seldom, however, so severe as to cause much annoyance. In time, a process of disintegration may be set up in them, eventuating finally in ulceration, especially if the part is habitually fretted or compressed. The general health never suffers.

In the treatment of these tumors nothing is to be expected from sorbefacient remedies. So long as they remain inactive, or are so situated as to occasion no inconvenience, they may be let alone; when the reverse is the case, they should be extirpated.

2. *Keloid.*—The keloid tumor, so called from its fancied resemblance to a crab, is also a peculiar hard fibroma of the cutis, first accurately described by Alibert, in his treatise on cutaneous diseases, in 1810. It is characterized by the existence of hard, semielastic, prominent ridges, of a cylindrical or rounded form, more or less discolored, and the seat of an unpleasant itching sensation. Processes, roots, or branches usually extend from it into the neighboring parts, the whole looking very much like the cicatrice of a burn.

The disease is generally described as being extremely infrequent; but, judging from my own experience, this is not the fact. I have notes of at least thirty cases, and many more have come under my observation of which I have neglected to keep a record. It occurs in all grades of society, in both sexes, in nearly all parts of the body, and at almost all periods of life. I have seen it at three years and a half, and repeatedly after the age of sixty. A number of my patients were negroes; but whether they are more subject to the disease than whites I am unable to affirm, although this is highly probable.

The exciting causes of keloid are not always the same. It sometimes arises spontaneously, and is then very liable to show itself in various parts of the body, as if the individual was laboring under a veritable keloid diathesis, as in two remarkable examples under my observation. In general, keloid succeeds to some local injury, sometimes of a severe, but more commonly of a trivial, character, as a scratch, puncture, or abrasion. In four of my cases it supervened, respectively, upon the operation of cupping, the application of a blister, the contact of nitric acid, and the cicatrices left by smallpox. In another instance it broke out upon a vaccine scar. In a young lady of seventeen, it was produced by the application of hydrate of potassium, employed for destroying an enlarged lymphatic gland of the neck. In several cases it followed upon the extirpation of tumors. Thus, in an elderly lady from whom I removed the right mammary gland, two well-marked keloid growths came on, soon after the operation, at the site of two small incisions made to ease one of the flaps with a view to more accurate approximation ; and the occurrence of the disease after the ablation of keloid tumors, both at the line of union of the edges of the wound and at the parts transfixed by the pins used for the twisted suture, is familiar to every surgeon. The most common causes, however, of keloid, so far as my experience extends, are burns and scalds, and I have also seen a considerable number of cases in which the disease was directly traceable to the irritation produced by wearing a bad form of ear ring. Young negresses are particularly prone to suffer from this source.

The period which intervenes between the occurrence of the exciting cause and the actual development of the disease is altogether uncertain ; in many cases it is very short, not exceeding a few weeks, or, at furthest, a few months ; on the other hand, however, the time is occasionally much longer. In several of my cases the tumors had acquired a large bulk in the space of a single year. Once fairly commenced, the disease generally proceeds with marked rapidity, especially when it is traumatic ; the same is also true, although not so generally, when it arises spontaneously. Thus, in an instance recently under my observation, an immense number of these excrescences appeared spontaneously upon different parts of the body within a few months after the first manifestation of the morbid action.

The peculiar external characters of keloid will readily be understood from the annexed drawing, fig. 246, taken from a patient of mine, a colored man upwards of fifty years of

Fig. 246.

Keloid Tumors.

age, whose body was literally covered with growths of this kind. They were particularly numerous on the neck and trunk, both in front and behind, and also on the shoulders and arms, while the forearms, hands, and lower extremities were entirely free from them. In size they ranged from a small Lima bean up to that of a sausage from six to eight inches in length. They were of all shapes ; some round or cylindrical, some elongated and flattened, some angular, some crucial, some crablike or full of processes, roots, or prongs; in short, nature seemed to have exhausted her ingenuity in devising figures for their representation. The surface of nearly all was rough, wrinkled, or puckered. Most of them projected from a line and a half to an inch and a quarter above the surrounding level ; some were isolated, others ran into each other, thereby adding still further to their grotesque appearance. Their consistence varied ; most of them were remarkably hard and firm, feeling very much like a mass of fibro-cartilage, with a slight

degree of the elasticity inherent in that tissue. In regard to their color, while some resembled the natural skin, the great majority were several shades lighter. The inter-

vening integument was sound up to the very borders of the keloid tumors, which were all distinctly circumscribed, and, with the exception of a very few, slightly movable.

The disease had begun early in life, but had for years been almost stationary. The man was otherwise well conditioned, his general health having all along been excellent; the only annoyance which he experienced was an itching or stinging sensation in some of the tumors, which, although at times very severe, especially when he labored under constipation, dyspepsia, or accidental overheating of the body, did not materially interfere with his sleep and other enjoyment.

In another case of spontaneous, universal keloid disease, in a young gentleman, eighteen years of age, a native of Cuba, the general health had always been excellent until twelve months previously, and there was no hereditary taint of any description. The tumors were, for the most part, of a rounded or oval shape, not very hard to the touch, movable, vascular, of a dusky reddish hue, free from pain, and quite tolerant of manipulation. In a few situations they formed distinct ridges, from a line to an inch in width, projecting prominently beyond the level of the surrounding surface. The hands and feet were covered with them, particularly the joints of the fingers and toes; they were also found on the legs, knees, buttocks, right arm, and elbow. The general health was somewhat impaired, the youth looked dyspeptic, and he labored under partial paralysis of the left superior extremity.

In white persons the keloid tumor is generally a few shades redder than the adjoining skin; occasionally, indeed, it has a very fiery appearance, and is pervaded by numerous, delicate, superficial vessels, in a state of habitual congestion.

A distinction has been made between keloid tumors by separating them into two varieties, the true and the spurious. The former, it is alleged, arise spontaneously, whereas the latter are always caused by some local injury. Such a division, however, is altogether arbitrary, inasmuch as the structure in both of the so-called forms of the disease is perfectly identical.

Keloid rarely, if ever, degenerates into malignancy. Of all the cases that have come under my notice, not one exhibited such a tendency. When excised, however, it nearly always speedily returns, rising, like a phœnix, with increased activity, from its ashes; so that the second state is generally much worse than the first. In some cases the tumors remain completely stationary for a long time, while, in others, they gradually advance until they have acquired a considerable bulk, when they usually become passive, and so continue for many years. Occasionally, in consequence apparently of prolonged pressure or local irritation, they take on ulcerative action.

In regard to their structure, keloid formations belong to the class of fibrous growths, described in the chapter on tumors, although an example is now and then met with in

Fig. 247.
Microscopical Characters of Keloid.

which the minute structure is very similar to that of spindle-celled sarcoma. According to Dr. J. C. Warren, of Boston, whose investigations have been confirmed by Dr. Neumann, of Vienna, they are developed from the walls of the small arteries of the cutis, and, in consonance with the arrangement of these vessels, the fibres of the tumor are all more or less parallel to its long axis. The tendency which they manifest to recurrence after extirpation is doubtless due to the formation of spindle cells in the external coat of the arteries, a change which extends for some distance beyond the limits of the morbid mass. The tumor, on section, presents to the naked eye a whitish, homogeneous aspect, or, if the mass is old, very much the appearance of an unripe turnip. It creaks slightly under the knife, and is of a dense, firm consistence, with very little elasticity. Hardly any vessels are perceptible in its in-

terior, but the surface of the growth is usually, as already stated, quite vascular, the vessels passing over it in distinct lines, more or less tortuous and varicose in their arrangement. The minute structure of keloid is well seen in fig. 247, drawn from one of my specimens by Professor Da Costa.

The *treatment* of keloid is altogether unsatisfactory. So far as I know, there is no remedy which exercises the slightest influence in arresting its progress or promoting its removal. Sorbefacients and alterants of every description, in every form of combination, and in every variety of dose, have been employed, and yet I am not aware of a solitary instance in which their exhibition, however protracted, has been followed by a cure. The different preparations of iodine, arsenic, chloride of barium, chloride of ammonium, and kindred articles, so serviceable in some other morbid growths, have all signally failed in effecting any beneficial change in this. The excessive itching, burning, or stinging, which is a source of such annoyance when the tumors are large or numerous, is best relieved, according to my experience, by a proper regulation of the diet, an occasional active purgative, the exhibition of the antimonial and saline preparations with Fowler's solution of arsenic, and the frequent use of the tepid bath, either simple, or medicated with carbonate of sodium or potassium, salt, or bran. Anointing the tumors occasionally with oil, glycerine, or mild pomatum will also prove serviceable. Benzoated zinc ointment, or an ointment composed of camphor and chloral, often affords great relief. Everything like pressure or local irritation must be carefully guarded against. If ulceration arise, only the most soothing remedies should be employed.

As to excision, my experience is decidedly opposed to it. In the many cases in which I have tried it, signal failure has been the result, the disease always recurring at the site

Fig. 248.

Molluscous Fibroma.

of the cicatrice in a short time, in some cases, indeed, as I know from ample personal experience, within the first four or five weeks. It is only when the tumors act obstructingly, as when they impede the opening of a natural outlet, or become a source of great disfigurement, that interference should be considered as warrantable. Possibly in some cases relief might be afforded by a plastic operation, but of this I am not able to say anything from personal experience.

In a case of an immense keloid tumor, encircling the neck, and causing serious inconvenience by its pressure, in a negro, twenty-eight years of age, an inmate of the Philadelphia Hospital, the late Dr. F. F. Maury succeeded, after three separate operations, in effecting complete riddance with the écraseur, the entire mass weighing nine pounds. A number of similar growths existed in other parts of the body. The man recoved without a single accident.

3. *Soft fibromas.*—Under the term *molluscous fibroma*, Virchow has described a form of cutaneous fibrous tumor, in which the growth, composed of a soft, very succulent, loose connective tissue, as in fig. 248, from that author, appears

Fig. 249.

Molluscous Fibroma.

to be derived from the fibrous structure of the papillæ. Varying in size from a millet seed to that of an adult head, the smaller ones are made up of round and spindle-celled tissue, while the larger tumors are composed of soft, poorly organized, fibrous tissue. The former are seated principally in the superficial layer of the cutis, from which they may readily be enucleated. Soft, almost to the point of fluctuation, they are generally multiple, covering the entire body, although their favorite seats are the face and trunk, giving rise in the former situation to the affection described by the older authors as leontiasis. Occasionally congenital, they are free from pain, not contagious, little disposed to ulcerate, and tardy in their development.

In its multiple form, molluscous fibroma induces general nutritive disturbances, which lead, in the course of time, to death from inanition. Its analogy to nodular elephantiasis of the genital organs is very great, the only difference being that the progress of the former is unattended with fever and local inflammation. The accompanying sketch, fig. 249, from a photograph of a Chinaman, kindly sent to me by Dr. J. G. Kerr, of Canton, affords an excellent illustration of this affection.

The treatment of these tumors does not differ from that prescribed for the ordinary fibrous growth. When they produce unsightly deformity, or occasion much inconvenience, they may be excised.

5. SARCOMATOUS TUMORS.

These tumors are uncommon in the skin. Occurring most frequently after the fortieth year, they are usually of the spindle-celled variety, and begin as a smooth, firm, elastic, reddish, or violaceous nodule, although they are occasionally ingrafted upon a mole, wart, or cicatrice, grow rapidly, and may attain a considerable bulk, at length ulcerating and becoming the seat of a more or less abundant and fetid discharge. No involvement of the lymphatic glands takes place, and the general health does not suffer unless the growth assumes malignancy. Recurrence is common after extirpation.

A case of round-celled sarcoma lately under my care, in a lady seventy-two years of age, very well illustrates the clinical nature of this affection. The tumor, about the size of a common orange, occupied the inside of the middle of the forearm, where it was first noticed about five months before, as a small, hard, movable lump. It rapidly enlarged, and in a short time assumed an angry and inflamed appearance, the skin giving way at several points, followed by a thin, sanious, offensive discharge, which eventually became very abundant and irritating to the surrounding surface, which, to an extent of several inches, was habitually red, tender, and deeply congested. There was occasionally a little shooting

Fig. 250.   Fig. 251.
Verrucous Sarcoma.   Nodule of Melanotic Sarcoma in the True Skin.

pain in the tumor, but the health was excellent, and the axillary lymphatic glands were perfectly sound. A section of the tumor after removal was found by Dr. Keen to be composed chiefly of small round and oval cells, with multiple nuclei, and with a moderate amount of friable, filamentary intercellular substance. The wound, which was only skin deep, healed very kindly, and up to the present time, some months after the operation, there is no evidence of recurrence. Verrucous sarcoma, which presents itself as an aggregation of enlarged papillæ, incrusted with an epithelial covering, as in fig. 250, from Lücke, is usually composed of small round cells.

Pigmented or melanotic sarcoma of the skin, fig. 251, nearly always coexists with melanosis in other parts of the body. In a case that was under my observation, some years ago, in a man, aged fifty-eight, it involved nearly all the principal organs, and, of course, finally proved fatal. In another instance, which I saw in the practice of the late Dr. George McClellan, an immense number of melanotic tumors existed in the skin and connective

tissue of the abdomen, varying from the volume of a small pea up to that of a mass the size of a large almond; they were of a firm, fibro-cartilaginous consistence, slightly movable, exquisitely painful, and of a bluish-black color. The remedy in this case was excision, a few of the larger tumors being removed at a time; the operation was repeated every ten or twelve days, for several months, when, as but little progress had been made towards a cure, the patient became discouraged, and declined further interference. He finally died, completely exhausted by the disease.

When melanotic sarcoma is confined to the integument, and occurs as a circumscribed tumor, the proper remedy is early and free excision; but under opposite circumstances, or when it coexists in other parts, or is extensively diffused through the cutaneous and connective tissues, all interference of this kind should be avoided, as likely to accelerate the fatal crisis.

6. MYOMATOUS AND NEUROMATOUS TUMORS.

1. MYOMA of the skin, composed of smooth muscular fibres, has occasionally been observed, as single or multiple growths, in the scrotum, nipple and its areola, trunk, extremities, penis, and labia. It is usually pedunculated; is smooth, hard, and of a rosaceous tint; varies in size from a pea to an orange, being generally of the volume of an almond; and grows slowly, and, as a rule, painlessly. The proper remedy is excision.

2. NEUROMA.—The only cases of neuroma of which I have any knowledge are those of Dr. Duhring and Dr. Kosinski. The tumors were multiple and composed of amyelinic nerve fibres. In the case of Duhring, numerous small, rounded, and excessively painful tubercles were situated upon the shoulder and arm; and excision of an inch of the brachial plexus of nerves, by Dr. Maury, was temporarily followed by diminution of suffering and decrease in the size of the tumors. In the case of Kosinski, the buttock and thigh were affected in a similar manner. Removal of an inch of the small sciatic nerve resulted, at the expiration of four months, in the almost complete disappearance of the nodules and the relief of pain.

7. PAPILLARY TUMORS.

The morbid growths comprised under this appellation include two varieties, the hard and the soft, the first consisting of warts, corns, and horns, and the second of moles and condylomas, or the excrescences situated about the anus, on the head of the penis and on the vulva, in connection with which organs they will be described.

1. WARTS.—Warts, or verrucous growths, are those peculiar excrescences, or prominences, so often seen upon the hands and face of young persons, although the old are by no means exempt from them. They are outgrowths of the papillæ of the skin, which are collected into a circular group, as seen in the adjoining sketch, fig. 251, from Follin, and covered with indurated epidermis. The intervals between the individual papillæ are occupied by a large number of transitional cells of the mucous layer of the epidermis. The vessels of the papillæ are enlarged and extend close up to their extremities. They sometimes occur in such numbers as to constitute a genuine verrucous diathesis. When this is the case, they are not only developed with remarkable rapidity, but are apt to attain an extraordinary size. A very painful and disagreeable wart occasionally forms under the nail, either in front or at the side. It occurs both on the fingers and toes, although much more frequently on the former than the latter. Of the exciting causes of warts nothing is known: they are often met with in several members of the same family, and instances are observed in which they betray a hereditary tendency.

Fig. 252.

Common Wart.

A wart is a hard, insensible excrescence, generally of a conical shape, more or less movable, and attached by a broad base, although sometimes the reverse is the case, the union being effected by a very narrow pedicle; its surface is rough, fissured, or tuberculated, and usually a few shades darker than the adjacent skin; its size seldom exceeds that of a common pea. When cut, it is painful, and bleeds somewhat. The fluid which follows a section of a body of this kind has been supposed, but erroneously, to be contagious, or inoculable. A wart of the face, arm, or shoulder sometimes becomes the seat of carcinoma, or sarcoma, especially when it is constantly rubbed or irritated.

The treatment of warts is very simple. In young persons, in fact, they often disappear spontaneously. The best local remedy is chromic acid, with equal parts of water, applied with a glass brush. It instantly turns the skin black, and forms an eschar, which drops

off in six or eight days, leaving a healthy, granulating sore, which soon heals. Tincture of iodine, acetic acid, dilute nitric acid, and sulphate of copper, also answer an excellent purpose. When the excrescence is attached by a very delicate pedicle, riddance is easily effected with the ligature or scissors. The verrucous diathesis is best counteracted by the exhibition of arsenic, or Donovan's solution. Excision is necessary when a wart displays a tendency to malignancy.

2. CORNS.—Corns, or clavi, consist in a circumscribed indurated overgrowth of the horny layer of the epidermis, the central portion of which is directed inwards towards the papillæ. They are caused by irritation of the superficial portion of the dermis and hypertrophy of the papillæ; affect different parts of the toes and feet; and are generally produced by wearing tight shoes and boots, whereby these organs are habitually compressed and even forced out of their natural position. A short, tight stocking occasionally produces a similar result. Corns are very variable in regard to their size, form, and consistence. They are usually distinguished into hard and soft.

Hard corns are dry, scaly, insensible callosities, occurring mostly on the dorsal surface of the toes, opposite the middle joints. All these structures are occasionally affected, but the great and little toes suffer much more frequently than any of the rest. These bodies are met with also in the sole of the foot, in the hollow or arch, and on the under part of the heel. Occasionally a very hard corn is found under the nail of the big toe, or between the nail and the fleshy part of the toe.

A hard corn, when fully developed, is lamellated, firmer at the centre than at the periphery, and furnished with a kind of central nucleus, core, or blunt cone, of a whitish, horny appearance, not unlike the eye of a fowl. A small, but distinct burse, containing a minute quantity of serous fluid, and sometimes a drop of blood, is almost always interposed between it and the dermis, the papillæ of which are depressed, diminished in number, or entirely destroyed. These apppearances are well shown in the adjoining sketch, fig. 253, from Follin. The hard corn consists of many layers with their convexities turned downwards; it is commonly of a circular shape, is either fixed or movable, and varies in size from the head of a pin to that of a dime. In many cases it has a kind of radiated root.

The hard corn, from a continuance of the pressure by which it is produced, becomes gradually a source of pain and tenderness, which are much increased by exercise, and are often accompanied by heat and swelling of the whole foot. In time the burse under the horny cuticle inflames, and pours out an unusual quantity of fluid, which distends the sac, and thus greatly aggravates the suffering. When matter forms, the pain becomes excruciat-

Fig. 253.

Structure of a Corn.

ing, the slightest touch is intolerable, and the patient is unable to use the limb. In such cases the lymphatic vessels are sometimes inflamed as high up as the groin.

Soft corns are always situated between the toes, usually opposite a joint or at their angle of union, and derive their characteristic features from being in a constant state of moisture, from the perspiration which collects between these parts; they are usually superficial, and are produced by wearing narrow-soled shoes, by which the toes are habitually squeezed together, bent at their articulations, or forced over or under each other. For this reason ladies are more subject to this variety of corn than men or the poorer classes of females. The soft corn is of a circular or oval figure, of a whitish, yellowish, or grayish color, with a radiated or horny-looking nucleus, and is seldom larger than a split-pea or half a dime. Occasionally it is broad, oblong, flat, and of a dark color, from the presence of extravasated blood. In some instances, especially in old people and in cases of long standing, the corn is very hard at the centre, has a small synovial burse, and consists of several distinct layers. From being constantly compressed, it is very painful, and remarkably prone to inflammation, suppuration, and even ulceration.

The *treatment* of corns consists in scraping away the thickened cuticle, and lightly touching them with nitrate of silver, or tincture of iodine, repeated occasionally until the cure is completed. This may be greatly expedited by washing the feet night and morning with cold water and soap, and afterwards rubbing them well with a soft, dry towel. The shoe, which should have a low, broad heel, should be accurately adapted to the shape of the limb, and all undue pressure carefully avoided, even from the seam of the stocking. When the toes are much deformed, or incurvated, they are to be kept apart by pledgets of lint, a piece of soft sponge, or strips of adhesive plaster passed from one to the other. When this cannot be done from their fixed position, amputation may become necessary. In

some instances it is useful to make the patient wear a stocking constructed on the principle of a glove, each of these stockings having a separate stall. A shoe made of buckskin or cloth sometimes affords great relief.

When corns are very tender, they should be frequently scraped with a blunt knife, and kept constantly covered with a piece of soap plaster, or a bit of linen spread with simple cerate to prevent them from becoming hard and dry. In some instances the pressure may be warded off by letting the corn project through a hole in the plaster, which ought then to be very thick, or consist of several layers. When the corn is seated in the sole of the foot, and this treatment is employed, it must be first covered with a piece of adhesive plaster, otherwise the weight of the body will cause the skin to project into the opening, and thus produce severe pain in walking. Occasionally it is necessary to cut a hole in the boot or shoe, or to wear a felt sole with a hole in it, to protect the corn from pressure and friction. All these means, however, are merely palliative, and, when they fail, nothing short of complete eradication will answer. The operation, which is seldom painful, is performed with a small narrow-pointed scalpel and pair of forceps, care being taken not to injure the sensitive skin beneath, and to soften the corn by previous immersion in warm water. When an abscess forms, it should be opened as speedily as possible, after which the offending part may be removed, or this may be postponed to another day. Sometimes the matter escapes by ulceration, leaving a fistulous sore with thick, irregular edges, and constantly bathed with a thin, ichorous fluid. In such a case nitrate of silver constitutes the best remedy.

When corns are inflamed, they cannot be treated with too much care, since, if neglected, they may give rise to serious mischief. The foot should be kept perfectly at rest, and it may even be necessary to resort to leeches and medicated fomentations. The knife should be used most cautiously. Several instances have fallen under my observation in which the cutting of an inflamed corn was followed by violent erysipelas and mortification ; and numerous cases are recorded in which these diseases, thus occasioned, have caused death.

Fig. 254.

Horny Excrescence growing from the Scalp.

3. HORNS.—The horny tumor, or keratoma, is met with principally in those regions of the body which abound in papillæ and sebaceous follicles, as the face and forehead. Of seventy-one cases collected by Villeneuve, not less than thirty-one occurred in these situations. They have been found on the lips, the ear, the penis, and the scrotum. I have in a number of instances seen well-marked horn-like excrescences on the free extremity of the stump after amputation. Several such growths are sometimes observed in the same person. Although they are most common in elderly subjects, I have met with two cases in children under ten years of age. They seem to occur with nearly equal frequency in both sexes.

The size, shape, color, and consistence of the horny tumor are subject to much diversity, depending on its age, and other circumstances. A length of three to six inches by half an inch to an inch in diameter, as in fig. 254, is by no means uncommon. In the British Museum there is a growth of this description, eleven inches in length by two and a half in circumference; and examples of a still more remarkable nature have been reported by authors. In that curious book, An Essay for the Recording of Illustrious Providences, by Increase Mather, are briefly mentioned

the particulars of the case of a "man that has an horn growing out of one corner of his mouth, just like that of a sheep; from which he has cut seventeen inches, and is forced to keep it tied by a string to his ear, to prevent its growing up to his eye."

The shape of these excrescences is usually conical, being larger at their adherent than at their free extremity, which is always somewhat tapering, and their direction is either spiral, twisted, or bent, very much like the horn of a sheep. In a case recorded in the New York Medical Repository for 1820, an enormous growth of this kind, measuring fourteen inches in circumference at its shaft, consisted of three distinct branches. The surface is generally marked by rough, circular rings, indicative of the successive steps of their development. Now and then it is imbricated, knobbed, or covered with small pearl-colored scales. In color the excrescences vary from a dingy yellow to a dark grayish, brown, bronze, or black, according to their age, and the amount of their exposure. They are more or less flexible, and of a firm, fibro-cartilaginous consistence. Their internal arrangement, as seen on a section, is longitudinally lamellated, as in fig. 255.

When burned, these formations exhale a characteristic animal odor. They are chiefly composed of albumen, in union with a small quantity of mucus, phosphate of lime, and chloride of sodium, with a trace of lactate of soda. On the addition of acetic acid, numerous epidermic scales become apparent, with all the characteristic properties of such structures. Under the microscope, the minute texture of these growths exhibits epithelial cells, which, according to Sir Erasmus Wilson, are of a flattened shape, closely condensed, and, here and there, fibrous in their arrangement. They are somewhat larger than those of the epidermis, and possess nuclei, for the most part of an oval shape, their long diameter measuring $\frac{1}{2500}$, the short $\frac{1}{3300}$ of an inch. The average size of the flattened cells is about five times greater than that of the nuclei.

Fig. 255.

A Section of a Horn, showing its Lamellated Structure.

Human horns are generally connected with hypertrophied papillæ, in which they probably take their rise. Their development is frequently directly traceable to the effects of chronic inflammation, or external injury, as a burn, wound, or contusion. When first observed, they are quite soft, semitransparent, and invested by a distinct cyst, which, extending over their base, is gradually and insensibly lost upon their trunk. Very soon, however, they become hard, and, assuming a darker hue, thus acquire the veritable properties of the horny tissue as it exists in the inferior animals. Their growth is always very tardy.

Although these excrescences sometimes drop off spontaneously, a cure rarely, if ever, follows such an occurrence; for, as the matrix remains, it soon becomes the starting-point of a new growth, which, pursuing the same course as its predecessor, may eventually acquire a similar, or even a greater, bulk. The proper remedy is extirpation, the whole of the epigenic cyst being included in two elliptical incisions, the edges of which are afterwards carefully approximated by suture and adhesive strips. When the operation is thoroughly executed, there is no chance of a recurrence of the morbid product.

4. MOLES.—Moles, or fleshy warts, are congenital spots, occurring upon various portions of the external surface of the body, usually of a dark, grayish, blackish, tawny, or brownish color, and closely covered with short, thick, almost bristly hairs. They project somewhat above the surrounding level, are usually a little harder than the natural skin, and are of various forms, of which the round and oval are the most frequent. Some persons are remarkably liable to the formation of moles, and it is then not uncommon to see them scattered over different parts of the body. The face, shoulder, neck, and arms are their most frequent seats. In size they range from a three-cent piece to that of a dinner plate.

These spots are due to pigmentation of the soft mucous layer of the epidermis and of the dermis, with hypertrophy of the latter and its papillæ, and hyperplasia of the hair follicles.

Long-continued local irritation, as that caused by friction, pressure, or want of cleanliness, may occasion ulceration in these bodies, but generally they remain perfectly stationary and innocuous. Not long ago, I excised from the back part of the arm of a gentleman of upwards of eighty a mole which had been a source of annoyance to him for thirty years. It had latterly become ulcerated, had often bled, and was the seat of a very fetid discharge. It was included in an elliptical incision, the parts healing kindly, and there being no return

of the disease. Moles, like healthy structure, may take on malignant action, the most common of which is the epithelial.

Moles only become the subjects of surgical interference when they cause serious disfigurement, or when they pass into ulceration. It has been proposed to get rid of them by mild caustic applications, as Vienna paste, chromic acid, or chloride of zinc ; but as such a procedure might be followed by keloid, the best plan always is to use the knife, the morbid structures being included in an elliptical incision, the edges of which are afterwards healed, if possible, by the first intention.

8. EPITHELIOMA.

Epithelioma of the skin differs from epithelial carcinoma of the mucous surfaces or of the junction of the latter with the integument in being, as a rule, superficial or more disposed to extend along the surface than to infiltrate the deeper tissues. The affection may be divided into two varieties, which differ widely in their clinical features and in the amount of destruction of the structures involved in the morbid action. They are known as cicatrizing epithelioma and rodent ulcer or cancer.

1. The *cicatrizing epithelioma*, a term which is synonymous with fressende flechte of the German authors and with the lepoid of Dr. Warren, the latter name having been applied to it from its resemblance to the bark of a tree, is most generally observed upon the face, nose, and forehead of elderly persons, usually males, of a delicate, florid complexion, with an habitual tendency to congestion of the capillary vessels, light eyes, and light brown, or reddish hair. Although occasionally single, I have more commonly found it to be multiple. In some instances, indeed, quite a number of spots are observed, scattered about in different directions, with intermediate healthy skin. It generally makes its appearance in the form of a small, circumscribed speck, not larger, perhaps, than a mustard seed, and of a dirty, grayish color, which becomes covered with a very rough, brownish crust or scale. This, falling off, is soon succeeded by another, of the same complexion, form, and consistence. Thus the disease is often kept up for many successive years. At last, however, superficial ulceration sets in, and the dermis is converted into a red, glossy, retracting cicatricial tissue, covered with a thin layer of epithelium. The progress of the disease is attended with hardly any pain ; but the patient is generally very much annoyed by itching, leading to an irresistible desire to scratch, which always aggravates it.

The precise derivation of cicatrizing epithelioma is undetermined, although it is highly probable that the morbid action is confined to the superficial stratum of the mucous layer of the epidermis.

The best remedy for this disease is non-interference. The rough, bark-like scale may occasionally be softened with a little dilute citrine ointment, or covered with a mixture of two parts of collodion and one of castor oil, to serve as a defence from the air. All irritating applications must be refrained from. If the disease is inclined to spread, the tissues may be destroyed with the Vienna paste, or removed with the knife, although it will generally be best to avoid all operative interference, as it is likely to aggravate the case by an early recurrence of the formation.

2. *Rodent ulcer*, Jacob's ulcer, cancroid, noli me tangere, flat or superficial epithelial carcinoma, is the phase of epithelioma, which in all probability is derived principally from the external root-sheath of the hair follicles or the involuted continuation of the mucous layer of the epidermis. The cells are smaller than those found in ordinary epithelioma ; they do not evince signs of activity and proliferation ; and they grow into the connective tissue of the cutis in the form of solid, anastomosing plugs or cylinders. When the new structure is fully developed, concentric globules of corneous epithelium are occasionally found in the plugs, as is well represented in fig. 256, from Dr. J. Collins Warren.

Rodent ulcer generally begins in the form of a hard nodule, pimple, or warty excrescence, which, after perhaps an existence of several years, ulcerates superficially and becomes covered with a crust. As the infiltration of the tissues progressively advances, the scab drops off, and leaves an ulcer which has a depressed or excavated appearance, with hard, raised, and rolling edges, and a mammillated bottom, composed of small, indurated granulations. There is little secretion, and at the advancing borders of the sore the orifices of the sebaceous glands, plugged by sebum, are very distinct. The progress of the disease is generally very slow ; or the malady, after having evinced a most destructive tendency, may suddenly stop, with all the appearances of a complete cessation of hostilities. A case has been reported to me where the morbid action, after having destroyed the greater portion of one cheek, with the corresponding antrum, has remained in a state of abeyance

for the last ten years, although it had been steadily pursuing its course for upwards of fifteen. Its march is occasionally remarkably rapid, great mischief being done in a few

Fig. 256.

months, being attended with the most frightful ravages and the most disgusting deformity. Thus, it may consume the whole of the nose, one cheek, the chin, the orbit, and forehead, and even extend to the dura mater and the brain, as in fig. 257, taken from a patient of Mr. Erichsen.

Fig. 257.

The affection progresses by destroying its own margins and by invading the continuous and the contiguous tissues; and as it advances there is often a tendency on the part of the older portion of the ulcer to cicatrize. During its course it appears to obliterate the bloodvessels and the lymphatics, so that the lymphatic glands and the viscera are never the seats of secondary tumors.

Rodent ulcer is a disease of advanced age. It evinces a remarkable predilection for the upper part of the face and head, its favorite situations being the cheek, the side of the nose, the eyelids, and the temple. The pain is generally slight; but now and then it is severe, being of a sharp, biting, darting or shooting character, and liable to temporary exacerbations from exposure, and atmospheric vicissitudes. The general health, at first entirely sound, becomes seriously affected during the progress of the disease; the appetite and sleep are impaired; the

Rodent Ulcer; Perforation of Skull and Exposure of Dura Mater.

strength declines; marasmus gradually ensues; and the patient, worn out by suffering, finally dies completely exhausted.

The great object in the treatment of rodent ulcer is to arrest the morbid action, either with the knife, or with some suitable escharotic, as the acid nitrate of mercury, chloride of zinc, Vienna paste, or Esmarch's powder. Excision, as a rule, deserves the preference. The operation should be performed as early as possible. Sometimes the actual cautery may be employed with advantage, its action being, seemingly, of a more repressive character than that of the knife. When an extremity is involved and the bone is invaded, amputation should be resorted to. The constitutional remedies are limited to anodynes and supporting measures, since internal agents are not of the slightest service in arresting the progress of the affection.

SECT. IX.—INSECTS IN THE SKIN AND CONNECTIVE TISSUE.

The skin and connective tissue are liable to be infested by certain insects, which, although not poisonous, may induce serious suffering, especially in persons of a nervous, irritable temperament. I refer more particularly to the chigoe and the Guinea worm.

The *chigoe*, which is very common both in this country, South America, and the West Indies, is a little insect, scarcely half the size of the smallest pin-head, which penetrates

the skin of the hands and feet, as well as of other exposed parts of the body, for the purpose of sustenance and hatching. It is a species of flea, with a rostrum as long as the body, of a pale-brownish, semitransparent appearance, with legs of a light lead color, which often deposits its eggs in immense numbers. The first effect is an itching sensation, which is soon followed by heat, redness, and swelling, and, ultimately, by an ugly, irritable, spreading ulcer. If the part, when it has attained this stage, be carefully examined, it will be found to contain a cyst, about the size of a pea, and of a bluish color, in which the ova live and multiply with astonishing rapidity. When a number of chigoes penetrate the skin together, the suffering produced by them may be so great as to cause violent constitutional disturbance, and even death.

The treatment consists in picking out the insect and its eggs with a fine needle, care being taken not to rupture the cyst, otherwise the young brood may produce further mischief. Clearance having been effected, the part is well washed with salt water, tobacco juice, or spirit of turpentine, and thoroughly painted with dilute tincture of iodine. The female slaves in the West Indies are said to extract these insects with great dexterity.

The Guinea worm, or little dragon, technically called *filaria medinensis*, also buries itself in the body. It is chiefly met with in tropical countries, particularly in Egypt, Arabia, Persia, Abyssinia, and Guinea, the inhabitants of which are often sorely afflicted by it. Of a white color, and of a filiform shape, it has an orbicular mouth, and a slightly pointed tail, its usual length being from five to twenty inches, and its thickness that of a small violin string. Its ordinary abode is the subcutaneous connective tissue of the feet and legs, although it is also found in other parts of the body, as the scalp, face, neck, scrotum, hands, and arms. It is commonly coiled up circularly, and is inclosed by a distinct cyst, which thus separates it from the surrounding parts. The animal enters the skin when quite young, and gradually increases in size, exciting intolerable itching, inflammation, swelling, and suppuration, often attended with fever, and sometimes followed by gangrene. The precise situation of the worm is generally indicated by a kind of boil, or a hard, ridge-like elevation. When ulceration sets in, the head of the creature usually protrudes at the opening, thus confirming the diagnosis of the case.

In the treatment of this affection, the proper plan is to cut down at once upon the part and extract the intruder. It is worse than useless to waste time in the application of leeches, liniments, and embrocations, which, so long as the cause of irritation lies buried under the skin, can produce none but the most transient effect. If the tumor is already open, and the head of the animal is protruding, extrusion may be promoted by gentle traction.

SECT. X.——AFFECTIONS OF THE HAIRS.

The principal affections of the hairs, surgically considered, are hypertrophy and atrophy.

Hypertrophy presents itself in several varieties of forms, as well as of situation, as in excessive length of the hair on the scalp, beard, or pubes, in extraordinary numbers, or in places which are naturally destitute of it. A redundant development of hair now and then occurs on the forehead, face, or neck. A male child, four months old, was brought to the College Clinic, in 1866, the greater portion of whose forehead, on the left side, was thickly covered with long hair, of the same color precisely as that of the scalp. The corresponding eyebrow was very heavy, and the countenance exhibited altogether a very singular appearance. In the female, hypertrophy of the hair occasionally exists in the form of a strong beard, nearly, if not quite, equal to that of the male. The affection is most common in barren women, of masculine figure and erotic temperament. An accidental development of hair is not unusual. Moles, certain nævi, and congenitally hypertrophied skin, are often covered with hair.

A redundant growth of hair becomes an object of treatment only when it occupies a part of the body that is naturally exposed to observation, as the forehead, face, or neck. The principal remedies are excision and evulsion. The former is more particularly applicable when the affected surface is of very limited extent, as in the case of a congenital mole, or an inconsiderable hypertrophy of the integument. Evulsion is effected with the tweezers, one hair after another being pulled out by the root. The operation, however, is not only painful, but seldom successful, inasmuch as the formative organ still remains, and there is, consequently, a constant reproduction of the hair. The same is true of the use of depilatories, formerly so much in vogue in the treatment of this affection. Most of these preparations are powerful caustics, their active ingredients consisting of quicklime and arsenic, in the form of orpiment, and hence, if great care be not observed in their

management, their destructive influence may extend much more widely than is desirable. Besides, if employed superficially, the hair bulbs will necessarily remain intact, and thus in a short time the new growth will be likely to be as vigorous as the original.

In the case of the child above alluded to, where the redundant hair occupied a large portion of the forehead, I dissected away the entire mass by carrying my knife through the substance of the skin, sufficiently deep to include the hair bulbs, and had the satisfaction to effect a complete cure. Very little bleeding attended the operation, and no unpleasant effects followed. The resulting scar was very trifling.

Atrophy of the hair and depilitation are natural consequences of advancing age, and of certain diseases, as typhoid fever, scarlatina, porrigo, psoriasis, and secondary syphilis. The falling of the hair is often temporary, and then probably depends upon some transient affection of the piliferous follicles. Baldness of the scalp generally begins at the crown of the head, whence it slowly extends in different directions, the hair bulbs gradually wasting and disappearing. I have seen five cases of secondary syphilis in which, in the course of a few months, every hair of the body dropped off, and was never reproduced. The baldness is sometimes congenital, as in the case of a child, four years of age, a patient of mine, whose entire body was destitute of hair.

The treatment of depilitation must be conducted with special reference to the nature of the exciting cause; for so long as this continues in operation little progress can be made towards a permanent cure. The general health, if at fault, must be amended, and the suffering surface excited with stimulating lotions, as solutions of zinc, copper, tannic acid, iodine, and nitrate of silver. The use of iodide of potassium in union with bichloride of mercury is indicated when there is a syphilitic taint of the system. In gradually gravescent baldness of the head, great benefit often accrues from cutting the short, stunted, and broken hair once a month close to the scalp. The operation imparts a new impulse to the piliferous follicles, and is frequently followed by great and permanent improvement.

CHAPTER II.

DISEASES AND INJURIES OF THE MUSCLES, TENDONS, BURSES, AND APONEUROSES.

SECT. I.——MUSCLES.

THE muscles are liable to wounds and lacerations, inflammation, atrophy, hypertrophy, and different kinds of transformations, especially the fatty, which occasionally exists in a very high degree, and over a considerable extent of the body. They are also subject to some of the morbid growths, and to the development of hydatids and serous cysts.

1. *Wounds.*——When a muscle is divided by a sharp instrument, or accidentally ruptured, its fibres immediately retract so as to drag the edges of the wound more or less widely asunder. The extent to which this separation may be carried varies, in general, according to the length and thickness of the muscle, from a few lines to as many inches. In transverse fractures of the patella, the action of the straight muscle of the thigh often draws the superior fragment from three and a half to four inches away from the inferior; and it is reasonable to conclude that fully as extensive a gap would be produced between the ends of this muscle if it were cut in two, or torn asunder. In rupture of the straight muscle of the abdomen, the edges of the subcutaneous wound have repeatedly been found to be separated from an inch and a half to two inches. In the operation for the cure of strabismus, the retraction of the posterior extremity of the divided muscle is seldom less than from four to six lines, and often even considerably more.

The above facts are highly interesting in a practical point of view, inasmuch as they point out the propriety of adopting prompt and energetic measures for effecting and maintaining apposition of the ends of the divided muscle; for observation has shown that the more accurate this is the more speedy and perfect will be the cure. If the edges are brought fully and intimately together, the union will necessarily require but a small quantity of plastic matter for its early and complete consolidation. If, on the other hand,

the gap amounts to several inches, either no union will occur, or it will be effected through the intervention of a large quantity of fibrous tissue, possessing none of the properties of muscular fibre. Hence the affected structures must always remain proportionately weak and disabled. But this is not the only inconvenience that follows such an accident; in wounds of the abdominal muscles, for example, the gap is sure to give rise to hernia, and it is easy to see that a deficiency of this kind elsewhere would hardly be productive of less serious effects. The only rational remedy under such circumstances, is the thorough union of the divided ends of the muscles by sutures, metallic ones being the best.

2. *Laceration.*—Rupture of the muscles is often produced by very trifling causes, the most common of which are leaping, or jumping across ditches or over fences, lifting heavy weights, or falls from a considerable height, in which the person makes a powerful effort to ward off injury. Cases are upon record of women having lacerated the abdominal muscles during parturition. Injuries of this kind are most likely to happen, other things being equal, when a muscle has undergone the fatty degeneration, which, by rendering its fibres soft and lacerable, acts as a powerful predisposing cause of rupture. Long-continued inactivity of a muscle, followed by sudden and violent contraction, may be mentioned as another predisposing cause of the accident.

The muscles which are most liable to rupture are the straight muscles of the abdomen, the psoas, deltoid, the two-headed flexor of the arm, the straight femoral, and the gastrocnemius.

The place where the rupture usually occurs is near the junction of the fleshy fibres with their tendons; but occasionally a muscle may give way at its middle, or, in fact, at almost any portion of its extent. In twenty-one cases of this affection analyzed by Sédillot, the rupture, in thirteen, took place at the insertion of the fleshy fibres into their tendons, while in the remainder it was seated in the body of the muscle itself. The laceration is sometimes limited to a few fibres; at other times it involves the entire thickness of a muscle, or of a muscle and its aponeurotic envelop. Finally, cases occur in which a number of muscles are ruptured.

The symptoms are not always well marked, especially when the affected muscle is deep-seated. In general, it may be assumed that such an accident has occurred, if, at the moment of some violent bodily exertion, as in leaping a ditch or fence, the individual hears a distinct noise or snap, like the crack of a whip, feels severe pain in some particular spot, and either falls, or has but an imperfect use of himself. Upon examining the suffering part, a vacuity will probably be noticed at one point, and an unusual prominence at another, followed by more or less discoloration and tenderness under manipulation. Occasionally the accident is attended with considerable hemorrhage, from the rupture of some of the smaller vessels. The pain is often very sharp, and rarely entirely disappears until after the primary effects of the lesion have measurably passed off.

Temporary lameness and inability to move about for some time are, generally, the only serious consequences to be apprehended from this accident, provided it is properly managed immediately after its occurrence. In most cases, a considerable period must necessarily elapse before the reunion of the torn structures will be sufficiently firm to justify their accustomed use. Occasionally violent symptoms supervene; and an instance has been reported to me of a young man who lost his life from rupture of the psoas muscle, death having been preceded by severe inflammation and infiltration of pus.

The treatment of this lesion cannot be the same in all cases, or under all circumstances. Whenever it is practicable, from the superficial situation of the affected muscle, its ends, whether cut or ruptured, should be freely exposed, and then carefully approximated by a sufficient number of stitches to hold them in contact until firm union has been established. For this purpose the threads should be carried nearly through the entire thickness of the muscle, the object being thorough apposition both of the superficial and deep portions of the wound. In case the muscle has been ruptured, the edges of the wound may be so ragged as to require some retrenching before placing them in contact, precisely as in a lacerated wound of the integument. If the precaution of stitching the parts be neglected, the results above adverted to will be inevitable, and it is, therefore, impossible to insist too strongly upon the importance of attention to this rule, which is so much neglected by surgeons.

The parts, being properly approximated, are next placed in an easy, elevated, and relaxed position, splints and bandages being employed for this purpose, if necessary, and they are then treated upon general antiphlogistic principles. If the ruptured muscle is deep-seated, our chief reliance must be upon rest and relaxation, conjoined with soothing

and astringent applications, along with suitable internal remedies, to moderate the resulting inflammation. In laceration of the muscles of the extremities, important advantage may always be obtained from the use of two rollers, applied in opposite directions, as the ends of the wound may thus not only be more effectually approximated, but the contraction of the fleshy fibres more easily controlled, than in any other manner.

3. *Inflammation.*—Inflammation of the muscles, or myositis, occurs in two varieties of form, the acute and chronic; both, however, are uncommon, and are chiefly observed as consequences of external injury, as blows, wounds, or contusions, such as are met with in fractures and dislocations; or as effects of gout and rheumatism. The sheaths of the muscles very frequently, if not generally, participate in the morbid action. When the inflammation is at all severe, considerable effusion of serum and lymph may take place, but it is seldom that the disease runs into suppuration, much less mortification. The latter termination is chiefly met with in erysipelas and carbuncle, in old, worn-out subjects, and in persons of different habits and conditions after violent external injury. It is easily recognized by the dark, greenish color of the fleshy fibres, by their softness and lacerability, and by their excessively fetid odor. The parts are detached in ragged shreds, and bathed in a thin, sanious dirty, and offensive fluid.

Acute inflammation of the muscles is characterized by excessive pain, of a sharp, darting character, or by dull, heavy, aching sensations, accompanied with a feeling of soreness, and aggravated by the slightest motion and pressure. In some cases, as when the disease supervenes upon fractures or the amputation of a limb, it is attended by a remarkable twitching or jerking, occasionally amounting to actual spasm, which only yields to large doses of anodynes, and hot, soothing applications.

Chronic myositis is not uncommon; like the acute variety, to which it generally succeeds, it is more frequently met with, surgically considered, as a secondary than as a primary affection. When long continued, it is very prone to give rise to fatty degeneration, softening, ulceration, and other changes, which it is often impossible to cure.

4. *Fatty Transformation.*—Fatty degeneration of the muscles is often, if not generally, a result of chronic inflammation, especially when conjoined for any considerable period with steady, persistent inactivity, or want of exercise. Whether inflammation, however, is always necessary to its production is still a mooted question, although it is highly probable that it is. When thus affected, the fleshy fibres assume a pale yellowish, whitish, or slightly reddish color, at the same time that they are unctuous to the touch, and so much softened as to yield under the most trivial force. On pressure, a clear, oily fluid exudes, which greases the finger, is highly inflammable, and is composed of elain, adipocire, and ordinary fat, in variable proportions. These substances are not deposited, as some have conjectured, between the fleshy fibres, but form actually a portion of their constituent principles, their proper tissue being found, when examined microscopically, to be filled with granules, partly interposed between their striæ, and partly replacing them.

The fatty transformation is most common, as well as most marked, in the muscles of the loins, hip, thigh, and leg of old persons affected with paralysis. It is likewise occasionally observed in the heart, and now and then in the muscles around unreduced luxations, large exostoses, and old, deep-seated ulcers. When the change is profound and extensive, it sometimes involves the corresponding tendons and aponeuroses, which, in consequence, lose their polished, satin-like lustre. The disease does not admit of cure.

5. *Ulceration.*—Ulceration of the muscles is an uncommon occurrence. It is chiefly noticed in phagedenic sores of the leg, extending successively through the integument, connective tissue, aponeuroses, and, finally, the muscles, which, however, generally resist its encroachments in a very remarkable degree. In some of these cases the fleshy fibres are in a complete state of fatty degeneration, of a whitish color, and so soft as to admit of being scraped away with the greatest facility. When the ulceration is slight, the restorative process usually proceeds kindly, and the breach is soon filled with healthy granulations. No special treatment is required in this disease, apart from the remedies ordinarily employed under such circumstances.

6. *Contraction.*—Another effect of inflammation of the muscles, or of the muscles and their fibrous envelops, is contraction of their fleshy fibres, leading to marked disorder of their functions, along, perhaps, with severe pain, and even great deformity, as is so often seen in wryneck, consequent upon inflammation of the sterno-cleido-mastoid and splenius muscles, and in the muscles of the thigh from the effects of hip-joint disease. In many of these cases the disease is obviously of a gouty or rheumatic character, and it then often occurs at a very early age, the immediate exciting cause being usually exposure to cold, or cold and wet.

In the treatment of myositis attended with contraction of the affected muscles, the first object should be to ascertain, if possible, the nature of the exciting cause, as to whether it is the result of rheumatism, gout, scrofula, or syphilis, or of external injury, as a sprain, twist, blow, wound, or contusion; for upon the knowledge thus derived must necessarily depend the character of our remedies, and the chance or otherwise of a cure. I have usually received marked benefit in these cases from the use of the wine of colchicum in combination with a full dose of morphia at bedtime; aided by active purgatives and diaphoretics, especially the warm bath, a well-regulated diet, and the frequent application of Granville's lotion in union with laudanum and soap liniment, thoroughly rubbed upon the affected parts. The muscular rigidity attendant upon a syphilitic state of the system is best treated with iodide of potassium, either alone, or conjoined with mercury.

In the more subacute or chronic cases of muscular contraction, great benefit may be expected from the use of the hot and cold douches, employed twice a day, and followed first by dry friction, then by the application of stimulating liniments, and finally by thorough shampooing. Frequent motion is also generally of great service, to break up adhesions, and to promote the absorption of effused fluids, upon which the affection so often mainly depends, as is observed in the shortened and rigid state of the limbs after severe fractures and dislocations.

7. *Atrophy.*—Atrophy of the muscles, of varying degrees, is occasionally observed; it may occur in any of the voluntary muscles, but is most common in those of the shoulder and hip, the deltoid suffering perhaps more frequently than any other. It may depend upon different causes, but generally it is produced by inflammation, palsy, or defective circulation; indeed, whatever has a tendency to impair the function of innervation, retard or diminish the supply of blood, or induce permanent inactivity in a muscle, may be considered as a cause of the affection. Hence it is found that the lesion is usually associated with paralysis, whether proceeding indirectly from disease of the cerebro-spinal axis, or directly from injury of the nerves distributed to the suffering structures. The muscles around luxated joints, especially those of the hip and shoulder, are frequently atrophied, either simply from want of use, or, what is more probable, the conjoint influence of inflammation and inactivity. In coxalgia, similar effects generally occur, the wasting usually involving all the muscles of the lower extremity. The fact that gout and rheumatism are frequently productive of atrophy of the muscles is familiar to every practitioner.

The extent to which the wasting of the muscles may proceed is variable. When it exists in a high degree, they may be reduced to mere membranous bands, pale, flaccid, and almost devoid of irritability; in some rare instances their fleshy fibres are completely absorbed, a dense fibrous substance being all that is left in their place; or, instead of this, they are found to be softened and transformed into fatty matter.

In the treatment of atrophy of the muscles, the first object should be to ascertain, if possible, the nature of the exciting cause, by removing which the lesion sometimes rapidly disappears of its own accord, or, at all events, under very simple management. Atrophy dependent upon imperfect supply of blood is often irremediable, and the same is frequently the case when it is caused by gout or rheumatism, or when it is conjoined with the fatty degeneration. The treatment of atrophy dependent upon loss of innervation, constituting what is called wasting palsy, will receive special attention in the chapter on the diseases and injuries of the nerves, where its consideration properly belongs.

Whatever the cause of atrophy of the muscles may be, much may be done, after that has been removed, towards effecting restoration, by the steady and persistent use of the hot and cold douches, stimulating embrocations, dry frictions, and regular, systematic exercise of the affected structures, educating them, so to speak, and thus gradually qualifying them, for the resumption of their appropriate functions.

8. *Tumors.*—Various morbid growths occur primarily in and among the muscles, the principal of which are the hydatid, cystic, fibrous, muscular, and erectile.

a. It is uncommon to meet with *hydatids* in the muscles, and I have myself seen only one case. The patient, a laboring man, twenty-five years of age, had accidentally discovered a swelling in the substance of the right deltoid muscle six months previously, when it was hardly as large as a hazelnut. At the time of my examination, it was of the volume of an almond with its shell, of a rounded, elongated shape, a little movable, and of a firm, fibrous consistence, with a slight degree of elasticity. Within the last few weeks the tumor had become somewhat painful, especially after exercise, and the pressure made in examining it was productive of considerable uneasiness. The skin over it was perfectly healthy.

The diagnosis of the tumor could not, of course, be determined before hand; what it

resembles most, especially in point of consistence, was an enlarged lymphatic gland, but the rarity of such a disease in this situation invalidated this conclusion, and left me in complete doubt as to the true nature of the case. It was too deep-seated for a sebaceous tumor, and it possessed none of the external characters of a fatty, fibrous, or sarcomatous one.

During the excision the knife penetrated the tumor, letting out a small quantity of thin pus; a circumstance which seemed, at the moment, to confirm the idea that the affection, after all, was simply a diseased lymphatic gland. On continuing the dissection, however, I soon found that there was a distinct cyst, which, being collapsed, was sepa-rated with some difficulty from the fibres of the deltoid muscle, in which it was Fig. 258. imbedded. The operation being completed, a small body, fig. 258, was picked up, which, on inspection, proved to be a globular hydatid, not more than six lines in diameter, and furnished with a distinct sucker. The cyst was very soft and thin, smooth internally, and externally filamentous.

Hydatid.

β. Tumors of a *cystic* character are occasionally met with in and among the muscles. In a case of this kind, which I saw with Professor Da Costa, the growth, occupying the upper and outer portion of the thigh, was nearly of the volume of an adult head. The patient, a female, fifty-eight years of age, in a fall down a flight of stairs, struck the limb severely, causing deep ecchymosis and great difficulty in walking. At the end of two months a swelling formed, which, gradually increasing, in less than a year, acquired the size above mentioned, being at the same time the seat of severe dart-ing pain, with considerable discoloration of the integument. The tumor fluctuated indis-tinctly, and a puncture with the exploring needle gave vent merely to a few drops of oily fluid. When removed by Dr. Brinton, it was found to be composed of a very thick, dense, fibrous cyst, filled with a sero-oleaginous liquid. The patient gradually recovered from the effects of the operation, but was troubled for a long time afterwards with pain in the limb and difficulty in walking.

The voluntary muscles are sometimes occupied by cysts containing blood, owing to the laceration of their fibres and vessels, the latter of which thus part with their contents. The effused fluid, coagulating, is gradually organized and eventually encapsulated, the covering being occasionally very thick, dense, and strong. In rare cases the blood is poured out spontaneously, or under the influence of very slight injury, as a blow or con-tusion. If the blood be partially devitalized at the moment of the accident, it will be likely to retain its fluidity, and to become ultimately, in great degree, if not entirely, de-colorized, so as to resemble an accumulation of serum, and act as a foreign body.

γ. Tumors of a *fibrous* and *myomatous* structure have been found in different volun-tary muscles, especially in those of the chest, shoulder, arm, and thigh; they are gene-rally of small size, slow in growth, and of firm consistence, with a tendency, now and then, to recurrence after excision.

δ. *Osseous* tumors are uncommon in the voluntary muscles. Mr. W. F. Teevan, in a monograph on morbid growths in this situation, has been able to find only three cases of the kind.

ε. Tumors of an *erectile* character have been seen in the sterno-mastoid, deltoid, semi-membranous, external oblique, long supinator, and semitendinous muscles. At the Col-lege Clinic, in 1870, I removed from the deltoid muscle of a girl, fifteen years of age, a cavernous tumor, which presented all the external features of a cyst.

SECT. II.—TENDONS.

The tendons, like the muscles, are liable to wounds and lacerations, but, unlike them, they very rarely, if ever, suffer from morbid growths. Inflammation of these structures is also very infrequent.

1. *Wounds.*—Tendons, when divided subcutaneously, readily unite through the inter-vention of plastic matter, without the occurrence of any considerable degree of inflam-mation. Indeed, the idea is very common at the present day that such wounds are al-ways repaired without inflammation, it being alleged that this process, instead of being necessary for this purpose, is a positive detriment. Such a doctrine, however, is unten-able. If its advocates mean that the inflammation is very slight, or not characterized by the ordinary phenomena, I perfectly agree with them; but if they wish to be understood as affirming that inflammation is entirely absent throughout, it is certainly not true.

When a tendon, such, for example, as that of the heel, is cut across subcutaneously, the first thing that is noticed is the retraction of the divided ends, so as to leave a distinct

gap between them, often ranging from an inch and a half to two inches, according to the size of the cord and its previous tension, or the degree of force employed in stretching the parts with which it is connected. Inflammation, generally of a very slight form, next takes place, and, soon after this is established, plastic matter is poured out, filling up the space between the two extremities of the tendon, and at the same time connecting them together. As the abnormal action subsides, fusiform cells form in the interior of the effused matter, and, the process of organization thus begun steadily advancing, the new substance is gradually converted into fibrous tissue, and this, in turn, at length into tendinous, which, however, although well adapted to fulfil the purpose for which it is intended, is, like all new tissues, a very imperfect type of the original. The reproductive process generally progresses very rapidly, so much so that the person soon acquires an excellent use of the affected parts. It is upon a knowledge of this property in tendon, when subcutaneously divided, to speedy reunion, that is founded the operation of tenotomy, one of the great improvements in modern surgery.

When a tendon is divided in an open wound, there is rarely, if ever, any spontaneous reunion, for the reason, first, that the ends retract too far to admit of thorough adjustment, and, secondly, that the wound nearly always suppurates; an occurrence highly inimical to adhesive action. All the earlier operations of tenotomy that were performed according to this principle failed, in consequence of the violence of the resulting inflammation.

The treatment of a divided tendon, then, with an open wound, is very different from that where the wound is subcutaneous. In the latter, the application of a bit of adhesive plaster to the puncture, to exclude the air, and a little attention to rest and position, make up the sum total of the surgeon's duty. In the former, on the contrary, the cut ends must be carefully approximated by the silver wire suture, the remainder of the wound being firmly closed; or the limb with which the tendon is connected must be placed in the most thoroughly relaxed position possible, in order to approximate its extremities, and thus afford them an opportunity of reuniting, an occurrence, however, which will certainly seldom take place under any circumstances, however propitious. The experiments of Dr. Levert, of Mobile, performed many years ago, prove that union between the divided ends of a tendon will be much more likely to proceed kindly and satisfactorily when the parts are held in contact by a metallic suture than by an ordinary one. Surgeons do not seem to have taken sufficient advantage of the results of these researches, and it is fortunate that the introduction of the wire suture by Dr. Sims has tended to recall attention to them.

Cases occasionally arise in which a tendon remains ununited, with a large intervening gap, long, perhaps, after the external wound has healed. In such an event it has been proposed to puncture the retracted extremities in different directions with a delicate tenotome, on the same principle that we sometimes perforate the ends of an ununited fracture. The procedure, however, seldom, if ever, succeeds, even in the most favorable circumstances. A much better plan is to expose the parts by a free incision, and, having pared the retracted extremities of the tendon, to unite them with silver wire, care being taken to keep the resulting inflammation within the limits of moderate fibrinous exudation. Since I first recommended this method, many years ago, successful cases of it have been reported, among others, by Dr. Warren Webster, of Illinois, Delore, of Lyons, and Dr. Simmons, of Sacramento.

2. *Rupture.*—Tendons are sometimes torn away from their sheaths along with the fleshy fibres into which they are inserted, hanging, perhaps, merely by one extremity: when this is the case, it would be useless to replace them, even if this were practicable, as there would be no likelihood whatever of reunion; on the contrary, severe inflammation and sloughing would be inevitable.

When a tendon is ruptured subcutaneously, a loud snap, like the crack of a whip, is generally heard at the moment of the accident, especially if the cord is a large one; the part is instantly deprived of its functions, and a well-marked gap, interval, or hollow is perceptible at the site of the injury. More or less inflammation follows, and a long time usually elapses before the patient regains the use of the affected limb. The tendon which is most liable to suffer in this way is that of the heel, its rupture being generally caused by violent muscular exertion, either for some special effect, as in the case of persons on the stage, or for the purpose of saving the body from a fall, as when the individual makes a false step. John Hunter ruptured his tendo Achillis in dancing.

The treatment of a subcutaneously ruptured tendon must be conducted by rest and complete relaxation of the affected structures, so as to enable us to bring the divided ends as closely together as possible. To effect this to the best advantage, special apparatus is

generally required, as well as the greatest attention and vigilance on the part of the practitioner. The time necessary for obtaining satisfactory union varies, on an average, from six to eight weeks.

3. *Dislocations.*—The tendons are sometimes dislocated, or thrown out of the canals in which they are naturally situated, in consequence of the laceration of the connecting ligaments, or retaining bands. The accident, which is most apt to befall the tendon of the two-headed flexor of the arm, as it runs along the bicipital groove of the humerus, is generally attended with severe pain at the site of injury, inability to move the affected limb, and more or less discoloration of the integument. Considerable swelling often follows, and, if the accident is overlooked, permanent lameness may result. Replacement should be effected as speedily as possible, a procedure which is usually very easy, provided the true nature of the case is recognized soon after its occurrence.

4. *Hypertrophy.*—Finally, the tendons are occasionally the subjects of hypertrophy, exhibiting an irregular, knotty appearance, which is not only unseemly, but sadly productive of discomfort. The affection is most common in gouty, rheumatic, and syphilitic persons, and is usually very readily detected both by touch and sight. The proper remedies are removal of the exciting cause, the exhibition of iodide of potassium, either alone or in union with mercury, and sorbefacient applications with massage.

5. *Thecitis.*—Inflammation of the sheaths of the tendons, technically called thecitis, may originate as an independent affection, or, as not unfrequently happens, it may begin consentaneously with inflammation of the parts which it surrounds and lubricates. In either event, the disease is often of a much more serious character than is generally imagined, nothing short, perhaps, of permanent lameness and deformity being the result. Various causes may give rise to thecitis; thus it is occasionally induced by gout, rheumatism, syphilis, and exposure to cold. On the other hand, it often supervenes upon external injury, as a sprain, blow, puncture, or contusion. In the hand and fingers it is frequently met with as a consequence of sprains of the wrist-joint, or fracture of the lower extremity of the radius and ulna. In regard to its character, it may be acute or chronic; more generally, perhaps, the latter than the former. Once fairly established, it is commonly removed with much difficulty, and is liable, as just stated, to be followed by the most disastrous effects.

The most common sites of thecitis are the sheaths of the tendons of the fingers, the wrist, elbow, feet, ankles, and knees; the disease may occur by itself, or in union with inflammation of burses and the lining membrane of the neighboring joints. In thecitis of the hands and fingers it is seldom that the disease exists except in this association, especially when it has been caused by a sprain, dislocation, or fracture of the radio-carpal articulation. In this condition, as I have had frequent occasion to notice, the inflammation is extremely liable to extend to the sheaths of all the tendons, as well as the joints of the fingers, rendering them stiff, tumid, and exquisitely painful. If the case is neglected or improperly treated, the whole hand becomes rigid; and the fingers, wasted and attenuated, present more the appearance of the claws of some of the inferior animals than the natural structures. The pain accompanying this form of thecitis often reaches as high up as the axilla, and I have known it to be so distressing at night as to deprive the patient completely of sleep for days together.

Thecitis, although apparently a trivial disease, assumes a most important character when it invades a number of thecæ simultaneously, or successively, and the gravity of the case is greatly augmented if there is at the same time considerable involvement of the neighboring joints, as when the attack takes place in the hands and fingers. Hence no time should be lost, and no pains spared, to get rid of the inflammation before it has produced any serious structural changes, particularly firm and extensive adhesions of the thecæ to their tendons. Leeches and tincture of iodine, either alone or in union with saturnine and anodyne fomentations, are the chief topical remedies upon which reliance is to be placed, while the patient is freely purged and restricted in his diet. Venesection and antimony will be necessary if the case prove obstinate. When the disease is associated with a gouty or rheumatic state of the system, wine of colchicum will be of service. In thecitis dependent upon a syphilitic taint, recourse must be had to iodide of potassium.

If the parts have become stiff in consequence of firm adhesions, the hot and cold douches, followed in immediate succession, along with frictions with sorbefacient liniments, embrocations, or unguents, steady, systematic passive motion twice a day, and the application of the bandage to support the affected structures, will gradually, although in general not under several months, effect restoration. In obstinate cases a mild mercurial course may become necessary, on the same principle that such a plan is occasionally adopted in

inflammation of other tissues attended with plastic effusions and morbid adhesions. When the disease is located in the hand, I have generally found it expedient to bandage each finger separately, and to support the parts upon a carved splint. In short, in many of these cases nothing but the most zealous and determined perseverance will enable us to effect a cure.

6. *Painful Crepitation.*—There is a singular affection of the tendons originally described by some of the French surgeons, as Boyer, Velpeau, Michou, and others, under the phrase of " painful crepitation." It is most generally met with in the tendons of the muscles of the forearm and hand, particularly the radial extensors at the outer and back part of the wrist, but is also liable to occur in those of the leg and toes. Now and then it is observed in the long head of the biceps. The disease evidently consists in inflammation of the sheaths of the affected tendons, followed by a deposit of plastic matter, roughening the contiguous surfaces, and thus occasioning the peculiar pain and crepitating sensation by which it is distinguished. The most common exciting causes are sprains, gout, rheumatism, and overexertion of the muscles. The affection is often attended by a certain degree of swelling of the limb at the seat of the morbid action, but there is rarely any decided dis- coloration of the surface, or, if there is, it readily disappears under pressure. More or less impairment of function is present. The characteristic symptom is a crepitation, which closely resembles the noise produced by rubbing coarse starch between the fingers, or the sound occasioned by treading on dry snow in very cold weather. In the forearm it may always be readily elicited by alternately pronating and supinating the limb. Great care is often necessary not to confound this species of crepitation with that of fracture. Its roughness and the mode of producing it will generally be sufficiently diagnostic of its nature.

The affection often disappears spontaneously, or under very simple measures, of which the most important are rest, sorbefacient lotions and liniments, and the hot and cold douches.

7. *Ganglion.*—A ganglion, as seen in fig. 259, from a clinical case, is a small circumscribed cyst, situated along the course of a tendon, to which it is intimately united. Composed of a single layer, which rarely exceeds the thickness of the dura mater, it is filled with a thin, yellowish fluid, more or less ropy in its character, and bearing a very strong resemblance, in its general features, to olive oil, the white of an egg, or a solution of gum arabic. In

Fig. 259.

Ganglion of the Extensor Tendons of the Hand.

cases of long standing, the contents of the sac are sometimes nearly entirely solid, consist- ing of a thick, ropy substance, of a dark color, not unlike currant jelly ; of masses, appa- rently, of semiorganized lymph ; or of small bodies similar, in shape and size, to cucumber seeds. In a ganglion of the hand upon which I operated some years ago, I observed the singular-looking bodies sketched in fig. 260. They appeared to be in different stages of development, and were evidently merely so many enlarged fringe-like processes of the synovial membrane, which had undergone fibroid transformation, and become detached in consequence of the continual friction of the tendon to which the sac was connected.

The volume of the cyst varies from a pea to that of a hickory nut ; it is of a globular or ovoidal shape, somewhat elastic, perfectly movable, free from pain, and unaccompanied by any discoloration of the skin. A sense of stiffness and of uneasiness, felt chiefly along the course of the tendon on which it is situated, sometimes attends its formation, and induces the patient to apply for advice. I have never known a ganglion to suppurate.

The tumor is most common in women, and is met with chiefly along the extensor tendons on the back of the hand, wrist, and lower extremity of the forearm. I have

seen several cases in which such a swelling was situated over the radial artery, the pulsations of which were so thoroughly imparted to it as to induce the belief, at first, that it was an aneurism of that vessel. A cyst of this kind in the palm of the hand is a rare occurrence. On one occasion I operated upon a young woman who had two ganglionic cysts, each of the size of a small bird's egg, upon the dorsal surface of the foot. The sole of the foot sometimes suffers in a similar manner. The affection now and then appears at an early age. I have met with it in a child only eight years old. The great majority of cases, however, occur in young adults.

Fig. 260.

Fibroid Bodies of Ganglion.

How this cyst is formed is still a mooted question. The probability, however, is that it is merely a sacculated expansion of the sheath of the tendons, and not, as some pathologists suppose it to be, a new formation. From the fact that it is most common in hard-working people, it, doubtless, owes its origin to inflammation, although it is seldom directly chargeable to external violence.

The most simple and trustworthy method of treatment consists in rupturing the ganglion, and scattering its contents into the surrounding connective tissue, where they are speedily absorbed. The operation may usually be performed with the two thumbs, but, if the cyst is old and very firm, it will be necessary to strike it with a book, as was done by the older surgeons, or to pierce it previously with a bistoury or tenotome. Evacuation having been effected, a compress inclosing a piece of coin or sheet lead is applied to the part, to promote the adhesion and obliteration of its cavity, the limb being maintained at rest until the resulting inflammation has subsided. When the ganglion is quite young, relief may occasionally be afforded by the application of iodine and systematic compression; ordinarily, however, such means are quite futile. Iodine is sometimes advantageously employed as an injection, in the same manner as in hydrocele. When the ordinary means fail, my practice is to cut up the sac as minutely as possible with a delicate bistoury, inserted subcutaneously, steady compression being afterwards maintained until obliterative inflammation has taken place. Both excision and direct incision must be avoided, as they are liable to cause erysipelas and to endanger the functions of the part.

What is called by authors the diffused or *compound ganglion* is merely a sacculated condition of one or more of the sheaths of the flexor tendons of the hand and wrist, and of the dorsum, sole, or inner side of the foot. The pouch thus formed is sometimes several inches in length, especially in the palm of the hand, by an inch or more in width, soft, fluctuating, irregular in shape, and, at first, free from pain, but liable, when inflamed, to more or less suffering and consequent lameness of the limb. In the older cases the sac often contains little bodies like melon seeds, and, under such circumstances, pressure always elicits a distinct crepitating sensation, characteristic of the nature of the affection. In the earlier stages of the disease the fluid is generally clear and thin, but as the morbid action advances, it becomes dark, turbid, bloody, and more or less thick, owing to the change of structure in the synovial sheath, which is often much thickened and studded with reddish and imperfectly organized granulations. The affection usually comes on without any assignable cause, and is much more frequent in women than in men, in whom it often occurs at an early age.

Rest, blistering, and iodinization afford temporary relief in this form of ganglion, but beyond this they do no good. The radical cure is based upon the use of the seton, consisting of two or three strands of well-oiled threads, introduced with a curved needle or eyed probe, and retained until a sufficient amount of inflammation has been excited to produce obliteration of the pouch. The limb meanwhile must be kept at rest, and every precaution taken to restrict the inflammation within proper limits. Excision is fraught with great danger.

SECT. III.—SYNOVIAL BURSES.

The synovial burses, bursæ mucosæ, or mucous pouches, exist in considerable numbers in various regions of the body, especially about the joints of the extremities, being small, semitransparent sacs, occupied by a thin, unctuous fluid. They are for the most part interposed between bone and tendon, tendon and tendon, bone and skin, or tendon and skin, their object being to facilitate motion and ward off pressure. Hence, they are

always most conspicuous in those situations which are habitually subjected to friction; and for the same reason they are occasionally developed to meet special contingencies arising from accidental causes, as the pressure of the shoe, crutch, or artificial limb. In club-foot synovial pouches are constantly formed upon those parts of the foot which, being partially displaced, are compelled to sustain the weight of the body. Altogether there are about one hundred and fifty of these sacs in the natural state.

The largest and most important synovial pouches, surgically considered, are situated on the acromion process of the scapula, the space between the hyoid bone and thyroid carti-lage, the condyles of the humerus and the olecranon process, the styloid projections of the ulna and radius, the tuberosity of the ischium, the great trochanter, the anterior superior spine of the ilium, the front of the patella, the condyles of the femur, the tuberosity of the tibia, the ankle, the calcaneum, and the heads of the first and fifth metatarsal bones.

The principal affections of the burses are inflammation, suppuration, induration and thickening, dropsical accumulations, the development of fibro-cartilaginous concretions in their interior, and contusions. It is not improbable that they may occasionally be the seat of some of the malignant formations; but as I have never met with any examples, it may be assumed that they are very uncommon.

Inflammation of these sacs may occur either in an acute or a chronic form, the latter being, however, by far the more frequent. The usual cause is inordinate and long-con-tinued friction conjoined with pressure. The disease may also be produced by blows, contusions, wounds, and punctures, and, in persons predisposed to gout, rheumatism, scrofula, and syphilis, by exposure to cold, or the sudden repulsion of the cutaneous per-spiration. The housemaid's knee, and the collier's elbow, are examples of inflamed and enlarged burses developed under the influence of concentrated and protracted pressure; another instance not less striking, is afforded by the bunion which so frequently forms over the inner surface of the metatarso-phalangeal articulation of the big toe. Constitu-tional syphilis, especially in its later forms, is an occasional cause of bursitis, having its origin either in the sac itself, or by extension from the neighboring tissues.

1. *Acute inflammation* of the burses is generally productive of very severe suffering; the pain is tensive, throbbing, persistent, and greatly aggravated by motion, pressure, and dependency; the swelling, which is often considerable, is usually due partly to exterior deposits, partly to an accumulation of synovial fluid, the quantity of which is commonly very much increased; the skin, of a dusky, reddish color, is deeply congested; and the functions of the affected structures are greatly impaired, if not completely arrested. Not unfrequently the swelling, is of an œdematous or erysipelatous character, pitting readily under pressure, and being the seat of a dull, heavy, prickling sensation. In the more severe forms of acute bursitis, there is usually considerable constitutional involve-ment, the patient being feverish, thirsty, restless, and troubled with headache, loss of appetite, and other disagreeable symptoms.

Upon cutting into the affected sac, its inner surface is found to be deeply congested, and roughened with lymph, while its cavity is filled with a bloody, serous, or sero-oleaginous fluid, often in considerable quantity, especially if the disease has been of some standing.

Bursitis occasionally passes into suppuration, the symptoms, when this is about to occur, suddenly assuming a more severe form, precisely as when matter is about to be deposited in any other part of the body. The pus, usually of a thin, oleaginous character, and intermixed with flakes of lymph, may find its way to the surface by ulcerative action, or it may discharge itself into a neighboring joint, although such an event is extremely rare, and is not likely to occur unless the joint has freely particatipated in the inflammation.

The treatment of this disease must be actively antiphlogistic; the part and system are kept perfectly at rest; leeches are applied to the affected surface, followed by anodyne and saturnine fomentations; the bowels, diet, and secretions are duly attended to; and the pain, which is generally severe, is controlled by morphia, or morphia, antimony, and aconite. If matter form, as denoted by an increase of pain and other symptoms, a free and early incision is made, the edges of the opening being kept asunder by a small tent to prevent reaccumulation. The milder forms of bursitis are generally easily combated by rest, cooling laxatives, and the application of tincture of iodine, or, what is frequently preferable, a blister, large enough to extend over the affected surface, and retained suffi-ciently long to produce thorough vesication.

2. *Chronic inflammation* of the burses occasionally gives rise to remarkable structural changes, the most common of which is an indurated and hypertrophied condition, the result either of long-continued interstitial deposits, or of the formation of adventitious membranes. However this may be, the walls of the affected sac are sometimes found to

be upwards of a quarter of an inch in thickness, and of a dense, fibrous consistence, without the slightest trace of its primitive characters. In this condition, the cavity of the pouch is generally very small, filled with altered synovial fluid, and roughened upon its surface, so as to exhibit an appearance not unlike that of a honeycomb. Now and then shreds of lymph are stretched across its interior, dividing it into different compartments. In cases of very long standing, partial ossification of the cyst has been noticed, but such an occurrence is very uncommon.

These chronic enlargements of the burses are often very obstinate and troublesome, resisting not unfrequently the best directed efforts of the surgeon for their removal. The remedies upon which most reliance is to be placed are sorbefacient applications, as iodine and chloride of ammonium, blisters, mercurial inunctions, and systematic compression. When these means fail, and the tumor is productive of pain and other inconvenience, our only resource is thorough excision, care being taken, especially if a large joint is close by, not to cut too widely away from the morbid mass, lest the synovial membrane of the articulation be inadvertently pierced, or so much injured as to excite violent inflammation.

3. Another result of chronic inflammation of these bodies is an accumulation of their natural secretions, giving rise to what is called *dropsy*, or hygroma, of which one of the best examples is afforded in the so-termed housemaid's knee. The fluid, varying in quantity from a few drachms to six or eight ounces, according to the size and situation of the affected burse, and the duration of the disease, is generally of a pale straw color, of a slightly unctuous consistence, and of a notably saline taste ; now and then it is reddish or brownish, and remarkably thick and viscid. It is readily coagulable by heat and acids, showing that it is essentially composed of albumen. The presence of the fluid is easily detected by the elastic and fluctuating character of the swelling, and very frequently a distinct friction sound and sensation can be perceived upon handling the tumor: if necessary, an exploring needle is used. The integument is free from discoloration, there is no enlargement of the subcutaneous veins, and the principal inconvenience experienced by the patient is of a mechanical nature. Now and then there is a good deal of pain, but more generally simply a sense of soreness and stiffness.

The size and shape of the tumor formed by these dropsical collections are subject to great diversity ; in general, it does not exceed the volume of an orange, or a goose's egg, but cases occur in which it reaches the bulk of a fœtal head, although this is very uncommon. Its shape is generally irregularly rounded or ovoidal, with a compressed, flattened appearance.

Dropsy of the synovial pouches may often be relieved, in its earlier stages, by the diligent application of iodine, astringent and sorbefacient lotions, and, above all, by blisters, conjoined, with rest, attention to the bowels, and the use of the bandage. In cases of long standing, however, such treatment is seldom of any permanent advantage, nothing short of a complete and radical change in the action of the secernent vessels answering the purpose. With this view, the water being drawn off with a trocar, the same remedies may be adopted as in the treatment of hydrocele, that is, injections of stimulating fluids, as tincture of iodine, nitrate of silver, or iodide of iron; or, what I deem better, because more certain, the introduction of a small seton, retained for a period varying from three to six days, according to the amount of the resulting inflammation. In either case, the part is carefully kept at rest, and every precaution used to prevent undue morbid action. When the tumor has become solidified and nearly of its origi-

Fig. 261.

Fibroid Bodies of a Synovial Burse.

nal size, it is an evidence that the seton should be withdrawn. From three to six weeks will usually elapse before a complete cure is effected.

The operation by incision is sometimes practised in these dropsical accumulations ; but

as it is not only severe, but liable to be followed by violent inflammation, sometimes seriously implicating a neighboring joint, it should be abandoned.

4. Intermixed with the fluid above described, or occurring independently of it, there are occasionally *loose concretions*, of a dense, fibrous, fibro-cartilaginous, or cartilaginous consistence, of a light yellowish, grayish, or whitish color, and of a flat oval form, not unlike small melon seeds. Their number is sometimes very remarkable, upwards of fifty having been extracted from a single pouch. The adjoining sketch, fig. 261, affords a good idea of the appearances of these bodies, as they are exposed on dissection, and also of the changes which the burse has undergone in consequence of their presence. When existing in considerable numbers, a careful examination will rarely fail to detect their true character. The symptoms which they occasion are such as usually attend chronic bursitis. More or less of a friction feel is generally present, and cases occur in which the little bodies may readily be pushed about from one place to another.

How are these bodies formed? Two theories have been advanced upon the subject. According to one, they consist essentially of plastic matter, originally poured out in soft, amorphous granules or flakes, which, increasing in size and density, are gradually moulded into a determined shape by the pressure of the surrounding parts, as well as by the friction which they exert upon each other as they are pushed about from place to place in their confined situation. The other explanation is that they are originally connected to the inner surface of the sac, from which they receive temporary support and nourishment; but, finally becoming detached, by the constant friction to which they are subjected, they present themselves as loose bodies, of varying shape and consistence. The latter theory is favored by the results of dissection, which not unfrequently shows some of these bodies as still firmly adherent to the inner surface of the affected pouch, and by the analogy which exists between them and the concretions met with in some of the movable joints, which are, apparently, always formed in this manner.

The only way to get rid of these bodies is to effect their extrusion by free incision, a drainage tube being afterwards placed in the bottom of the sac, to promote its obliteration.

Bodies, closely resembling small *hydatids*, are occasionally found in these pouches. J. Cloquet met with an instance in which there were upwards of one hundred and forty, varying in size from one to three lines in diameter, nearly transparent, and of a lenticular shape. They were situated in the large burse between the great trochanter and the tendon of the gluteal muscle.

5. *Contusions* of the burses are produced by violent blows and falls, and are followed either by acute inflammation or by a collection of blood in their interior, which generally undergoes changes similar to those witnessed in an apoplectic effusion, terminating in a fibrinous mass of varying firmness and density. When the contusion has been very severe, the extravasated blood remains fluid, and is converted into a dark, grumous mass, of the consistence of syrup.

The tumor formed by the extravasated blood is easily recognized by its sudden development in the situation of a normal burse after external violence, by its well-defined, circumscribed form, and by ecchymosis of the surrounding parts. It is always soft and fluctuating at the beginning, and sometimes it retains this feature throughout, although it generally soon becomes comparatively firm and hard, from the coagulation of its contents. If the sac be not too much distended, the clots may be felt through its walls, and a very distinct crepitation may be elicited by crushing them between the fingers.

Accumulations of blood in the burses disappear spontaneously, or under very simple measures, as rest, refrigerant, astringent, and sorbefacient lotions, and systematic compression. If inflammation and suppuration set in, the sac must be laid open. When the case proves obstinate, subcutaneous evacuation, followed by compression, will be necessary.

SECT. IV.—APONEUROSES.

The aponeuroses, considered by themselves, offer very little of interest in a surgical point of view, since their diseases are not only infrequent, but very imperfectly understood. From the intimate relations which they sustain, on the one hand, to the muscles, and, on the other, to the connective tissue, it is obvious that there can be but few diseases or injuries, of a serious character, of these structures, without more or less mutual involvement. At the same time, it is evident that the aponeuroses, from their peculiar arrangement, must necessarily, in many cases, play a very important part in preventing the extension of morbid action to the muscles which they serve to inclose, just as the periosteum impedes the propagation of disease to bone, and, conversely, from bone to the

surrounding textures.   This barrier, of course, is often broken in both cases, and then the ravages of the morbid action will be likely to be both rapid and extensive, as we see exemplified in the worst forms of erysipelas, carbuncle, and other affections, in which every variety of structure is rudely and indiscriminately assailed by inflammation, not unfrequently terminating, in a few days, in the destruction of an entire limb.

Acute aponeurositis is an uncommon occurrence, and is chiefly observed as a consequence of external injury, or as an effect of erysipelas, carbuncle, and whitlow.   Gout and rheumatism are generally believed to be seated exclusively in the fibrous envelops of the muscles; but the probability is that the tendinous, ligamentous, and bursal structures are nearly always implicated along with them, the two diseases sometimes beginning in the former, and sometimes in the latter, but usually ultimately attacking all.

A bad form of inflammation of the aponeuroses is occasionally produced by punctured wounds, especially when occurring in the palm of the hand and the sole of the foot, in persons of broken constitution and dissipated habits, or nervous temperament.   The disease soon assumes an erysipelatous disposition, and leads to excessive suffering, both local and constitutional: occasionally it is followed by tetanus.   Inflammation of these structures manifests but little disposition to pass into suppuration, ulceration, or gangrene.

Chronic inflammation of the aponeuroses is much more common than the acute, and leads to various alterations of structure, as thickening, atrophy, induration, and contraction, often followed by serious, if not irremediable, deformity.   Sometimes they are affected with slight ossification, the new substance presenting itself in the form of bony spicules; and cases are met with in which, from long-continued pressure, they are remarkably attenuated, and pierced with numerous apertures, giving them a sieve-like appearance.

The treatment of aponeurositis is conducted upon ordinary antiphlogistic principles. Anodynes must be exhibited in full and repeated doses to relieve pain and nervous symptoms; if plethora exist, or the local action is very severe, blood must be taken from the arm and by leeches from the affected parts; the bowels must be freely moved; and recourse must be had to saline and antimonial medicines.   Free incisions are made if much tension is present, or the formation of matter is threatened; followed by medicated fomentations and emollient poultices.

Aponeurositis dependent upon a gouty, rheumatic, or syphilitic state of the system, must be managed according to the general principles of treatment laid down for the relief of these affections; by colchicum, iodide of potassium, and mercury, in combination with other suitable means.

Sarcomatous and fibrous tumors, especially the spindle-celled variety of the former, are frequently met with in connection with the aponeuroses.   The fact of this occurrence need only be mentioned, as they obey the same laws here as in other parts of the body.

CHAPTER III.

DISEASES AND INJURIES OF THE NERVES.

SECT. I.—WOUNDS AND CONTUSIONS.

NERVES that are divided readily unite, and, after the lapse of several months, their structure and functions are restored.   In order, however, that the connecting medium shall be useful, the interval between the two extremities must be very short, otherwise each end may become expanded into a bulbous mass, having all the characteristics of a neuromatous tumor, similar to that which occasionally forms in a stump after amputation, and liable, like it, to become the seat of neuralgia.   It is worthy of notice that a nerve, slowly divided with a ligature, will generally unite more rapidly and completely than one divided with a sharp knife; in the former case there is commonly very little retraction of the ends, whereas in the latter they sometimes separate to a considerable distance, thus requiring a larger quantity of new material to fill up the gap.

When a nerve is cut completely across, the parts to which it is distributed are necessarily deprived of their functions, an occurrence which, consequently, serves as a diagnos-

tic sign of the accident. Thus, if the nerve be one of motion, the parts will be paralyzed, while, if it be one of sensation, they will be divested of sensibility. If the division be only partial, the loss of function will, of course, be partial also. In general, the structures beyond the seat of injury feel numb and heavy, with a sense of tingling, prickling, stinging, or burning. When the section is complete, there is always a remarkable diminution of temperature in the parts supplied by the affected nerve, seldom amounting to less than six, eight, or ten degrees. The structures remain for a long time sore, tender, painful, and prone to inflammation, and eventually they become greatly atrophied. The capillary circulation is seriously disturbed ; the vessels are habitually congested, and the skin is of a pale, livid hue, and easily impressed by atmospheric changes. In cases of long standing, the papillæ of the skin waste and shrink, and there is a material decrease of tactile sensibility.

The recent observations and experiments of Létiévant, Arloing, Tripier, and others have shown that, " despite the division of a nerve, there always remains, in the parts it supplies, a certain amount of sensation, if it be a sensory nerve ; of motion, if it be a motory nerve ; or of both, if it be a mixed nerve." These functions, which are at first very imperfectly performed, gradually increase in power with the lapse of time, and are evidentally due to the agency of anastomotic nervous filaments, the restoration being the same in principle as the restoration of the circulation after the ligation of an artery. The paralysis which supervenes upon the division of a nerve of motion is ultimately followed, in every case, by more or less muscular atrophy. Sensation is relatively more marked than motion, but, like the latter, it never attains the normal standard, except when the ends of the divided nerve are completely reunited, and is liable to be influenced by accidental conditions, especially by inflammation and œdematous swelling.

Wounds of the nerves are treated upon the same general principles as wounds of other structures. When there is no serious loss of substance, the divided ends should be as closely approximated as possible by attention to position, and by suture of the neurilemma, introduced with a very fine needle. A suture will be particularly serviceable when a large trunk has been severed, or when there is inordinate tendency to separation in the ends of the cord. The operation is very simple, and, if carefully performed, almost free from pain. The best substance is the carbolized catgut ligature, the ends being cut off close.

A similar procedure may be adopted when a large nerve has been severed, but has failed to unite. An incision being made down to the nerve, the two ends are carefully retrenched, and then tacked together by several points of suture, apposition being favored by stretching of the nerve and by attention to the position of the parts in which it is contained.

Suturing of divided nerves was advocated in the first edition of this work, issued in 1859, and since then numerous cases have been reported in which the operation was attended with the most gratifying success. The operation, in fact, is now one of the established procedures in surgery. Experience has shown that no harm results when the suture is pushed through the entire thickness of the nerve, neurilemma and all.

Nerves, when *punctured*, pricked, or partially divided, usually occasion severe pain, of a neuralgic character, extending up and down the affected parts, and attended with muscular weakness, perverted sensation, convulsive movements, and derangement of the general health. Such effects not unfrequently follow venesection at the bend of the arm, from injury sustained by one of the subcutaneous nerves. The proper remedy is complete division of the affected filament, either subcutaneously, or, when this is impracticable, by free incision. The operation, however, is not always permanently successful, owing to the deep impression which the lesion has made upon the general system. Besides, the divided extremities of the nerve are very apt to take on diseased action, either by being incorporated in the original cicatrice, or by being expanded into a species of neuroma. When this is the case, the proper procedure will be free excision instead of subcutaneous section, the ends, if not too widely separated, being afterwards united by suture.

Severe effects often follow *contusion* of the nerves, the parts to which they are distributed becoming numb, cold, withered, more or less painful, and, ultimately, almost entirely useless. Effects of this kind sometimes succeed to accidents, apparently, of the most trifling character. The nerves, so far as an opinion can be formed without the light of dissection, soon become inflamed, and are often irretrievably ruined, being effectually and permanently disqualified for the performance of their functions. It is hardly probable that these effects are due, as has been conjectured, to mere concussion of the nerve-substance ; for, if this were so, they would be much more transient, as

well as less severe. What corroborates the idea that inflammation is deeply concerned in the production of the secondary suffering is the fact that the parts, although seriously crippled at the start, do not evince much derangement until the disease is established in all its intensity.

Concussion of the nerves has been very ably described by Professor Willard Parker, who considers the accident as similar to concussion of the brain, the nerves receiving a shock eventuating in a sudden suspension of their functions. In a paper upon the subject, in the New York Journal of Medicine for September, 1856, he has related six cases illustrative of the nature of the injury. When the paralysis, which is generally temporary, subsides, the affected nerves are in danger of being assailed by inflammation, which, if it cannot be prevented, must be treated in the usual antiphlogistic manner. A long time frequently elapses before recovery takes place, the nerves remaining weak, irritable, and incapable of performing their proper functions. The limb supplied by the affected cords is soon exhausted by exercise, and is the seat of a dull, aching, tired sensation, which is always aggravated by exertion, especially if carried beyond a given limit ; in time, it becomes cold, atrophied, and, in great degree, useless. The general health also suffers, although the disease never proves fatal.

The treatment, in the first instance, is by rest, absolute and unconditional ; and, after the nerves have recovered from the immediate effects of the injury, by passive exercise, by slapping with a fringed towel wrung out of iced water, followed by massage and dry friction, and by attention to the general health, which, in the more severe forms of the accident, is always materially, if not seriously, impaired.

Severe pain is often produced by *compression* of the nerves, without, so far as can be determined, any particular disease of the nerves themselves. In aneurism, for example, of the larger arteries, the patient often experiences extreme suffering from this cause. The pain, in this case, is either sharp and darting, as in certain forms of neuralgia, or of a burning, tearing, boring, or gnawing character, especially if there is at the same time erosion of the osseous and cartilaginous tissues.

When the nerves of the distal portion of an extremity are injured, the fingers and toes are peculiarly prone to suffer, becoming, at first, inflamed, swollen, glossy, œdematous, and excessively painful, and afterwards, as more remote effects, atrophied and deformed, with various eruptions, ulcers, disease of the nails, and desquamation of the cuticle. Such affections are always difficult to manage, and often resist every attempt at a perfect cure.

Finally, the nerves are occasionally the seat of *foreign bodies*, introduced during the infliction of wounds, which they thus serve to complicate. Various kinds of substances may thus be carried in, as portions of clothing, pieces of wood, glass, porcelain, or iron, and fragments of bone. Denmark has related a case in which part of a bullet was imbedded in the radial nerve ; and Dupuytren met with one in which the end of a lash was buried in the ulnar nerve.

The immediate effects of such accidents are violent pain, spasmodic contraction of the muscles, loss of appetite and sleep, and great disorder of the health. Tetanus and neuralgia are also sufficiently common. The slightest motion and pressure always aggravate the local suffering.

The only remedy is removal of the foreign body, the presence of which is generally indicated by the seat of the pain. Sometimes the substance may be distinctly felt with the finger. When the suffering persists, it may be necessary to excise a portion of the affected nerve.

SECT. II.—TUMORS.

Various kinds of tumors, as the myxomatous, fibrous, sarcomatous, fatty, and cystic, have been found in the nerves, but their occurrence is very uncommon, and their discrimination is not only difficult, but frequently impracticable. Such growths, which seldom attain much bulk, probably always begin in the interfibrillar connective tissue, from which, as their development proceeds, they gradually extend to, and ultimately more or less seriously involve, the proper substance of these cords. The neuromatous tumors, described in a previous chapter, consist mainly of myelenic and amyelenic fibres. Cysts, occupied by a gelatiniform, serous, hematoid, calcareous, or osseous substance, have been met with in different nerves, especially in the larger trunks of the extremities.

Mr. C. H. Moore, of London, in 1866, described a very curious case, perfectly unique

in character, of arterio-venous tumor of the popliteal nerve, in a woman, thirty-one years of age, who had been struck in the middle of the ham with an iron pump-handle. It presented itself in the form of a vast cyst, shaped like a double cone, occupied by serum, black clots, and loose fibrin, interspersed with small clusters of white corpuscles, and consisted essentially of an expanded and hypertrophied condition of the component elements of the nerve, the fibres of which were disparted in such a manner as to resemble, in their mode of arrangement, the fleshy columns of the heart. The inner surface of the cyst had a smooth, shining appearance, and was marked by two orifices, one representing a large vein, and the other a small artery, which had thus poured their contents into the interior of the sac. When Mr. Moore first saw the case, nearly two years after the accident, the tumor completely filled the ham, and projected backwards in two prominent lesser swellings, which seemed to be partly fluid and partly solid, and which might have been mistaken for a large burse, so liable to form in this situation. The tumor was exquisitely tender on pressure, as well as the seat of severe pain, and violent pain, with a sense of tingling, was also felt in the leg and foot. An exploratory incision revealed the true nature of the disease, but as the cyst could not be dissected out, and as it would have been improper, on account of the woman's health, to allow it to suppurate, amputation was at once performed, and life thus preserved.

Bertrand met with a cystic tumor in the upper part of the median nerve, of the size of a hen's egg, in a man eighty years of age. It had never occasioned any pain, and was filled with sanguinolent fluid, intermixed with clots of blood.

The treatment of these tumors, whether benign or malignant, resolves itself into three distinct procedures:—1st, the removal of the morbid structure by a careful and patient dissection, with as little disturbance as possible of the proper nerve substance; 2dly, the excision of the affected portion of the nerve; and, 3dly, amputation of the limb. The first of these procedures would, for obvious reasons, be inapplicable to malignant growths, and the second could not be performed with safety when the tumor, benign or malignant, involves one of the principal nervous trunks of an extremity, as the operation might be followed not only by serious paralysis, but by extensive, if not fatal, mortification. Amputation should never be performed, unless it has been clearly ascertained, by a most careful inspection of the morbid mass, that it is the only available expedient. In a case recorded by Moutard-Martin excision of a malignant tumor of the median nerve was followed by the development in the brain of a similar growth, which caused the death of the patient.

SECT. III.—TETANUS.

The term tetanus is a generic one, employed to denote a peculiar affection of the nerves, characterized by violent contraction of the voluntary muscles, with irregular intervals of partial, although seldom of complete, relaxation. Different names have been devised to designate the disease, according to the nature of the predominant local symptoms occasioned by the affected muscles. Thus, when the muscles of the lower jaw are spasmodically contracted, so as to prevent the patient from opening his mouth, the word *trismus* is employed; or, to use a common expression, the person is said to have locked jaw. When the body is bent forcibly forwards by the action of the abdominal muscles, the affection is denominated *emprosthotonos*, and *opisthotonos* when it is drawn backwards by the dorsal muscles. The term *pleurothotonos* is used when the body is drawn to one side, which, however, is a very rare occurrence. A distinction of much greater importance is that of tetanus into traumatic and idiopathic, acute and chronic. The disease occasionally comes on within a few days after birth, and is then designated as infantile tetanus, the *trismus nascentium* of authors.

In this country, especially in its more temperate latitudes, the surgeon has to deal chiefly with traumatic tetanus, the idiopathic variety being extremely infrequent. Cases of it, however, occasionally occur in the more tropical States of the Union, especially in South Carolina, Georgia, Mississippi, Florida, Louisiana, and Texas; while in the West and East Indies it is sufficiently common. The tetanus of new-born infants is met with chiefly in the southern and southwestern States of North America, in consequence, apparently, of injury sustained in the ligation of the umbilical cord. Infantile tetanus seems to have at one time been very common in certain portions of Europe. Thus, it is asserted by Dr. Joseph Clark, that in the year 1782, of 17,550 children born in the Lying-in Hospital of Dublin, 2944 perished from this cause alone within the first fortnight after birth.

Traumatic tetanus, to which the ensuing remarks are more particularly intended to

apply, is not peculiar to any age or to any particular pursuit ; but is met with at all periods of life and in all classes of society. The young, however, suffer more frequently than the aged, and it is particularly liable to occur in persons of a nervous, irritable temperament. Ill health, especially disorder of the digestive apparatus, grief, anxiety of mind, and whatever has a tendency to depress the energies of the system, powerfully predispose to its development. Women are quite as liable to the disease as men, but the greatest number of cases occur among the latter because they are much more exposed to its exciting causes. Blacks and mullattoes suffer more frequently from tetanus than whites. In some portions of the West Indies the disease is almost exclusively confined to the colored population.

Traumatic tetanus occasionally assumes an epidemic tendency. In 1858, numerous cases of the disease appeared in rapid succession in several of the London hospitals, the attack having often followed upon the most trivial injuries and operations, as the ligation of a hemorrhoidal tumor or the amputation of a finger. In one of these institutions not less than nine deaths occurred from tetanus within two months.

Causes.—The causes of traumatic tetanus are, as the term implies, various kinds of external injury, as punctured, lacerated, contused, and gunshot wounds, burns, scalds, abrasions, compound fractures and dislocations, and surgical operations, as amputations and the excision of tumors. A number of cases have been recorded in which tetanus was produced by salivation. Some of the most trivial accidents are, at times, sufficient to occasion the disease. Thus, cases have been observed in which it followed the application of the scarificator in cupping, the introduction of a seton, and the extraction of a tooth. In three cases of tetanus under the care of Dr. Richard J. Levis, at the Philadelphia Hospital, the disease, in one, was occasioned by a slight scald of the back of the hand and wrist ; in the second, by frost-bite of the feet, and, in the third, by several Vienna paste issues made for the cure of varicose veins of the leg. Dr. John Lodge has mentioned to me the case of a youth, fourteen years of age, who died from locked jaw, caused by a slight scratch on the ball of the thumb, received three weeks previously. Baron Larrey has recorded an instance in which it was caused by the lodgment of a fish bone in the fauces. Examples of tetanus, consequent upon the ligation of the iliac, femoral, and carotid arteries, have been recorded by Brodie, Dazille, and Dudley. I have met with it as an effect of the injection of a hydrocele ; now and then it follows upon parturition. The fact is, in persons of a nervous, irritable temperament, any injury, however trifling, may readily induce the affection, especially in hot and damp states of the atmosphere, or during sudden transitions from heat to cold. Exposure to cold draughts, by which the body is suddenly chilled, is, under such circumstances, extremely liable to provoke an attack.

In our larger cities numerous cases of tetanus have of late years been caused by injuries inflicted with the " toy pistol" during our 4th of July celebrations, at the time when the thermometer was high up in the nineties. Of the many persons, chiefly boys, that were wounded in Philadelphia, on that day, in 1880, thirty-three, as I am informed by Dr. J. Sabastian Miller, perished from this disease, most of them within the first ten days. The lesions were in almost every instance inflicted upon the fingers, and the majority of them were apparently of a very insignificant character. The average duration of the cases was about ten days. In Baltimore, in July, 1881, upwards of twenty fatal cases of tetanus occurred from this cause.

The influence of injuries upon the production of tetanus is apparently much less than is generally supposed. Thus, of 3668 cases of operations, large and small, wounds of all kinds, injuries and contusions, burns and scalds, and compound fractures, treated at Guy's Hospital during a period of seven years, only 23, according to Mr. Poland, suffered from this disease.

The effect of cold air, when permitted to play directly upon the body, is well illustrated by what occurred after the battle of Ticonderoga, in 1758. The wounded were exposed the whole night after the action, in open boats upon Lake George, and the consequence was that nine of them died of locked jaw. During our war with Great Britain, most of those wounded by fire-arms on board the frigate Amazon, before Charleston, were attacked with tetanus on the fourteenth day, from a sudden change of very wet and cold weather following a long drought. Wounded soldiers lying on damp or wet ground, are particularly prone to attacks of this disease. Thus, after the battle of Bautzen, where the men were left all night on the field, exposed to severe cold, more than 100 were seized with tetanus ; and similar effects were witnessed after the engagement at Dresden, from the suffering induced by the sudden transition from a hot to a cold, chilly atmosphere.

The injury inducing the disease may be situated upon any part of the body. It was at one time supposed that lesions of the head and face were singularly exempt from tetanus, but more enlarged experience has demonstrated that, although it does not occur with the

same relative frequency as when the cause is seated in other regions, yet its invasion after such accidents is by no means uncommon. Injury of the inferior extremity is more prone to be followed by tetanus than a similar affection of the superior extremity; and everybody knows how remarkably liable the disease is to supervene upon wounds involving the tendons and aponeuroses of the hands and feet, especially of the latter. Lesions of the nerves themselves are peculiarly dangerous in this respect, more particularly when they are of a punctured character, or when they are limited to a partial division of their fibres and neurilemma, by a blunt instrument, as a piece of glass or a rusty knife. Fatal cases of tetanus from the ligation of nerves have been reported by Larrey and other surgeons.

The extent of the injury does not, so far as can be judged, exert any material influence upon the production of the disease, as it has been known to follow, on the one hand, the most insignificant scratch, and, on the other, the most frightful wound. I believe, in fact, that it may be assumed, as a general principle, that the danger of the occurrence of tetanus is, other things being equal, almost in direct ratio to the diminutive size of a wound. This is certainly true of a majority of the cases that have fallen under my personal observation, an apparently trivial injury, mostly a little puncture, having served as the exciting cause.

Symptoms.—The period which intervenes between the occurrence of the injury and the development of the disease is liable to considerable variety. Generally it ranges from four to ten days. In some instances well-marked symptoms supervene within several hours after the receipt of the injury; and, on the other hand, the attack may not occur under eight or ten weeks. In rare instances the disease does not appear until after the wound that provoked it is completely closed, owing, doubtless, to some lurking irritation in the nerves of the affected parts, or to the retention of some foreign substance.

Although tetanus may come on suddenly, with hardly any premonition, yet, in general, the attack is preceded by various anomalous nervous sensations which but too clearly foreshadow its approach. The most important and reliable of these precursories are, a feeling of malaise or universal uneasiness, aching in the muscles, stiffness about the lower jaw, pain in moving the head, and difficulty in protruding the tongue. The wound, if any exist, commonly puts on an unhealthy appearance, discharging a thin, sanious fluid, and manifesting no further disposition to heal. After these symptoms, which are often attributed by the patient to the effects of cold, have continued for a variable, but usually a very short, period, others, more bold and decisive in their character, set in, leaving no longer any doubt respecting their true nature. The jaw now becomes firmly locked; the faculty of mastication is completely abolished; attempts at deglutition excite spasm in the throat, with a sense of impending suffocation; and there is an indescribable distress in the precordial region, extending from the ensiform cartilage backwards towards the spine,

Fig. 262.

Opisthotonos.

as if the chest were tightly encircled by a cord. The muscles of the back and abdomen are rigidly contracted, and, in no long time, those of the extremities become similarly affected. When their action is very violent, the spinal muscles may shorten themselves so much as to draw the trunk into a distinct arch, the body resting only upon the occiput and heels, the affection thus constituting the variety of tetanus called opisthotonos, illus-

trated in fig. 262, from Bell. The opposite state of this, emprosthotonos, is extremely uncommon; for, although the abdominal muscles are usually very firmly contracted, being often as hard as a board, yet it is seldom that they are able to counteract the extensor muscles of the back to such a degree as to bend the head and chest forwards. The disease having reached this stage, may be said to be completely and characteristically established. Frequent spasms now occur, convulsing and agitating the whole frame, and greatly increasing the general suffering. The teeth are firmly clenched; the eyes are fixed in their sockets, and have a wild, unnatural expression; the nostrils are expanded; the corners of the mouth are retracted; the countenance has an old, haggard, and withered look; the respiration is laborious and hurried; and the smallest quantity of fluid is unable to descend the fauces and œsophagus. So great, in fact, generally, is the impediment to deglutition, that the very sight of water is a source of suffering. The pain is usually severe, particularly about the jaw, throat, chest, and spine; while the general sensibility of the surface is so excessive that the slightest breath of air is often sufficient to bring on violent spasms.

Fever is seldom present in traumatic tetanus, even when it has reached its height, although the thirst is generally very considerable; the pulse, which rarely exceeds eighty, eighty-five, or ninety in the minute, is soft and regular, except, perhaps, during the violence of the muscular spasms, when it may be considerably agitated, small, and feeble; the tongue, at first moist, becomes gradually dry and brownish; the stomach is extremely torpid; the bowels are generally obstinately constipated; the urine is scanty and high-colored; and the skin is hot and bathed with a copious perspiration, which is occasionally very clammy and offensive, especially towards the latter stages of the disease. The mind is usually unimpaired.

Although such is the most common course of the disease, yet more or less irregularity occasionally arises, giving the symptoms somewhat of an anomalous character. Thus, there may be little or no pain; the throat may be free from uneasiness; the respiration may be gasping, or performed with a sort of catch; the eyelids may be half closed and the ball fixed; the orbicular muscle of the mouth may be firmly contracted over the teeth; and the extremities may remain completely relaxed and powerless. Epilepsy, hysteria, and delirium are sometimes noticed. The skin is, occasionally, remarkably hot, the temperature in the axilla, in some cases, having been found to range as high as 100°, 110° and even 112° Fahr. A complete remission of the symptoms is one of the anomalies of the disease, extending sometimes over a period of several weeks, as in an instance reported by Dupuytren. Duval refers to several cases in which the disease assumed the form of an irregular ague; and Mr. Morgan, of London, saw two patients in whom the spasm, instead of affecting the muscles of the jaw, primarily attacked the muscles of the part injured. I recently attended, with Professor Wallace and Dr. George T. Barker, a young lady of seventeen, who, in consequence of severe irritation of the upper jaw, arising from disease of one of the canine teeth, was seized with tetanic symptoms, attended with locked jaw, pain in the epigastrium, back of the neck, face, and lumbar region, and the most violent opisthotonos. The paroxysms during the first twenty-four hours recurred with great frequency, often, indeed, every five or ten minutes, but afterwards, under the influence of hypodermic injections of morphia, aided by the use of chloral and quinine, they became less frequent, although they did not completely disappear under several weeks. The peculiar feature in this case was the entire absence of locked jaw during the intervals of the paroxysms, the attack having evidently been one of hysteria associated with tetanus.

Diagnosis.—The diagnosis of tetanus rarely, if ever, presents any difficulties. In general, the history of the case alone is quite sufficient to determine its true character. The only disease with which it can be confounded is hydrophobia, but the symptoms of the two affections are so very different that none but the most heedless practitioner could possibly commit such an error. The period of latency in hydrophobia is, on an average, not less than a month, while tetanus is usually developed in from five to fourteen days from the infliction of the injury which provokes it. Besides, in rabies there is an absence of locked jaw and of opisthotonos, which constitute such striking features in tetanus.

One of the most valuable diagnostic symptoms of tetanus is the terrible distress in the precordium; it is usually described as of a painful, dragging nature, and is no doubt dependent upon spasmodic contraction of the diaphragm. Coming on early in the disease, it generally continues to its close, and is nearly always attended with opisthotonos, the head and shoulders being drawn, as it were, instinctively backward, to relieve pain and to favor the introduction of air into the lungs. In tetanus, the muscular contraction is steady and persistent, although liable to frequent and sudden exacerbations; in hydrophobia

it is clonic, occurring paroxysmally, and having distinct intermissions. In tetanus, swallowing is difficult, chiefly by reason of the impossibility of separating the jaws; in rabies, it is dependent upon spasm of the throat and œsophagus; in the former, the mind is calm and unaffected; in the latter, it is often powerfully excited, and, at times, even furious.

Tetanus, especially in its chronic form, has sometimes been mistaken for rheumatism, from which, however, it is always readily distinguishable by the history of the case and the absence of spasm in the muscles of the jaw.

Poisoning by strychnia closely simulates tetanus. There is, however, no locked jaw; the patient is able to open his mouth and swallow; the agitation, trembling, and convulsions are more violent; the symptoms come on suddenly, and rapidly disappear when the dose is small, or death soon occurs when the quantity is large.

Prognosis.—The prognosis in traumatic tetanus is extremely unfavorable. In the great majority of cases death occurs from the third to the fifth day; and if an instance of recovery is occasionally met with, it only goes to confirm the general law of the mortality of this affection. In an experience of fifty years, I have seen but three cases where the patient escaped with his life, and then only after a protracted and painful struggle. When the disease has once fairly commenced, the tetanic spasms generally continue to recur, with more or less severity, until they prove fatal. There are no reliable signs which can serve to guide us in regard to the prognosis in this affection. The previous state of the general health, the age of the patient, and the character of the pulse, afford no clue as to the probable issue of the case. The young and the robust fare no better, in this respect, than the old and infirm. Both alike perish from its attacks. The danger is undoubtedly always, other things being equal, in proportion to the violence and duration of the paroxysms, and it has been found that any tendency to chronicity is generally so much in favor of ultimate recovery; although patients sometimes live for several weeks, and then die from the effects of the malady.

Of 415 cases of this disease tabulated by the late Dr. R. O. Cowling, of Louisville, Kentucky, 233 recovered, and 182 died, the mortality being greatest in children under ten years of age, and least between ten and twenty years. Professor D. W. Yandell, from a careful analysis of these cases, finds that persons are most likely to recover from acute tetanus when the attack occurs subsequent to the ninth day after the injury, and that, when the symptoms have lasted fourteen days, restoration is the rule, and death the exception, apparently independently of the treatment. Of 363 cases of traumatic tetanus that occurred during our late war, 336 terminated fatally. Of 27 reported cures, the disease was of a chronic character in 23.

The manner in which death occurs is not well understood. In some instances it is, apparently, caused by suffocation, from spasm of the muscles of the larynx; occasionally it results from mere exhaustion, life being worn out by the intensity of the suffering; and in a third class of cases it may probably be induced by spasm of the heart, interrupting the passage of the blood to the lungs and brain.

Pathology.—It might reasonably be supposed that a disease which is characterized by so much violence during life, would leave some traces of its existence after death; but, to show how erroneous such a conclusion is, it is only necessary to refer to the fact that all the dissections that have hitherto been made of persons dead of this affection have utterly failed to throw any satisfactory light upon its pathology and morbid anatomy. Many statements have been reported with reference to these dissections that are entirely without foundation; in fact, in not a few of the cases, natural or accidental appearances have been confounded with morbid, and lesions have been described which existed only in the imagination of the examiners. From the circumstance that tetanus is essentially a nervous affection, the brain and spinal cord, as well as the nerves emanating from them, and even the great sympathetic, with its plexuses and ganglia, have all been most thoroughly scrutinized in numerous instances, and that, too, by some of the ablest men in the profession, and yet, notwithstanding all this, we are no wiser now in regard to the actual lesions of this disease than surgeons were centuries ago. The whole subject is, in truth, still a mystery. I have myself made several dissections of this kind, and have witnessed others, amounting, perhaps, altogether to eight or ten, without having, in a single one, observed any morbid appearances that could justly be ascribed to the effects of the disease. It has been noticed in several instances that the nerves leading from the wound which caused the attack were in a state of inflammation, their substance and neurilemma being congested and discolored.

Of the true pathology of tetanus, then, nothing whatever of a satisfactory nature is

known; that it is essentially an affection of the nervous system, or of the nerves of particular muscles, must be admitted from the symptoms which characterize it; but in what the peculiar change consists, and to what extent it is carried, are points in the history of the lesion of which we are completely ignorant.

Treatment.—The treatment of this obstinate, and, unfortunately, too generally fatal, disease, is altogether of an empirical character. That this should be so is not surprising, when it is remembered how completely ignorant we are of its pathology, and the fact that there is hardly an article of the materia medica, of any reputed efficacy, that has not been employed, either singly, or in various forms and modes of combination, for its relief. Although patients occasionally get well of this disease, under circumstances, apparently, the most desperate, yet, when the practitioner comes to analyze his treatment, in the true spirit of philosophy, he is generally compelled to confess his ignorance as to the share which his remedies may have exerted upon the fortunate event, and to acknowledge that accident, rather than his own skill, performed the cure. However this may be, it is certain that the disease sometimes either wears itself out, or yields to the most insignificant measures, while at other times it resists the best directed efforts of the ablest and most experienced practitioner. The chances, indeed, of effecting any good, when the malady is fairly established, are very slender in any case, however mild. Hence, whatever is done should be done promptly, and with a view to a prophylactic rather than to a curative result.

One of the first and most important indications in traumatic tetanus is the removal, if possible, of the exciting cause, which is, of itself, occasionally sufficient to effect a cure. Thus, if any foreign body remain in the wound, or in contact with the living tissues, the surgeon cannot too speedily extract it, especially if there is already some evidence of approaching disease. Sometimes a vicious cicatrice may keep up the tetanic irritation. Many years ago, I attended, in consultation with Dr. Buck, a young girl of fourteen, who had locked jaw from having been accidentally hurt, nearly a month previously, in the right cheek, by a small splinter of wood. Although the substance was immediately extracted, yet the parts continued to be tender, being, at times, even quite painful, and in less than a week tetanus set in. When I saw the case, free use had already been made, without any material benefit, of anodynes and antispasmodics, along with an occasional purgative, and the cheek had been leeched and repeatedly painted with iodine. The girl was pale and feeble, and had lost her appetite. Upon examining the original site of the injury, I found a small, circumscribed spot, exquisitely tender under pressure, and of almost fibro-cartilaginous hardness. This being carefully dissected out, no more paroxysms occurred; and in a few days, with the aid of iron and quinine, wine, and a generous diet, complete recovery ensued.

Amputation of the wounded part has occasionally been performed; and, judging from the statistics that have been published upon the subject, there is reason to believe that the operation has now and then proved successful. Nevertheless, few surgeons would, probably, be found to be so venturous as to remove a leg or an arm on the approach of such a disease, and none certainly would be foolish enough to attempt the expedient after it is fully established. In the one case, the possibility is that the affection might yield to other and milder means; and, in the other, as the disease is no longer one of a local character, but diffused, as it were, through the system, it is difficult to see how amputation, however early performed, could be of any benefit in arresting the morbid action, unless it be upon the principle of substituting a fresh and clean wound for one of an inflamed and irritable character. An interesting case, bearing directly upon this point, fell under my observation, in a patient of Dr. Mattingly, of Kentucky. The man, who was fifty years of age, was a stout, healthy farmer, of a nervo-sanguineous temperament, who, about five weeks previously, had the fore and middle fingers of the right hand, between the second and third joints, severely mashed by the passage of the wheel of a wagon, the phalanges being completely comminuted, and supported merely by a few shreds of integument. A physician, shortly after the accident, removed the injured parts with the scissors, and, binding up the ill-formed stumps, sent the man home, a distance of thirty-five miles. Excessive pain soon ensued, followed, at the expiration of the time above specified, by well-marked symptoms of tetanus. Five days after this, while the patient was under the influence of chloroform, I removed the mutilated fingers at the metacarpo-phalangeal joints, the whole hand being at the time much swollen and exquisitely tender, the tongue coated, the pulse hard and accelerated, and the system irritable from the want of sleep. The tetanic spasms continued for several days after the operation, but they became gradually lighter, shorter, and less frequent, and in a few weeks all symptoms of the disease had entirely disappeared.

How far the recovery in this case was due to the amputation of the affected fingers, it would be difficult to determine; but it is reasonable to suppose that the operation was serviceable by ridding the system of a mass of irritation and disease, which, if it had been permitted to continue, might have proved highly detrimental, if not destructive, to the patient.

In regard to the treatment of the wound itself, it cannot be doubted that prompt attention to it is of great moment. The remedies should generally be of the most soothing character, consisting of warm water-dressing, or emollient cataplasms, with a liberal admixture of laudanum, powdered opium, or, what is better than either, sulphate of morphia. If the parts are girded by inflammatory engorgement, or various kinds of deposits, as will be likely to be the case when the wound is of a punctured character, free incisions must be made, the knife being carried thoroughly through the tissues in every direction. A similar method should be adopted when there is reason for suspecting the lodgment of foreign matter. The practice, at one time so common, and, perhaps, not yet sufficiently exploded, of pouring irritating fluids into the wound, or of applying escharotics, cannot be too severely censured, as it must inevitably increase the suffering, and aggravate the disease.

I have no experience with excision of the nerves connected with the injured structures; an operation said to have sometimes been successfully performed by foreign surgeons. Such a step could only be justified in the case of the smaller nerves, and then, I presume, all the good that would be likely to accrue from it might readily be accomplished by the free division of the affected parts. Excision of the larger nerves might be followed by permanent paralysis. Stretching the nerves has occasionally succeeded in traumatic tetanus, and is worthy of further trial.

The patient must be carefully protected from the contact of cold air. Exposure of the body to a direct current is often, of itself, sufficient to bring on an attack of tetanus in a susceptible, nervous person; and, after the attack is fairly established, such an occurrence never fails to aggravate the spasms, rendering them both more frequent and violent. The atmosphere of the room should, moreover, be perfectly warm and dry, experience having shown that cold and moisture combined are extremely prejudicial in all affections of this description.

The most important internal remedies, undoubtedly, are anodynes and antispasmodics, of which opium, chloroform, Calabar bean, tartar emetic, aconite, camphor, assafœtida, and Indian hemp occupy the highest rank. They should be administered in large doses, with a view to an immediate and decided impression upon the general system, and should be given either by themselves or in various states and degrees of combination.

The most eligible preparations of opium are the acetated tincture and the salts of morphia, particularly the sulphate. Opium in substance is objectionable, on account of its insolubility, the stomach, under such circumstances, being extremely torpid, and unable to act upon it. For the same reason, a much larger quantity of laudanum and morphia is required to produce their specific effect than in ordinary diseases. If the patient be young and robust, or when the spasms are violent and obstinate, the anodyne should be combined with tartar emetic, in doses sufficiently large to relax the system. The latter remedy is sometimes employed by itself, and cases have come under my observation where it seemed to have effected a complete cure. I am satisfied, however, that its efficacy will always be materially enhanced by its judicious combination with morphia. The most prompt and efficacious method of administering morphia is by hypodermic injection, from a third to half a grain being thus introduced, either alone, or in union with the fiftieth of a grain of atropia, two or three times in the twenty-four hours, according to the violence of the suffering.

Aconite is a medicine of great efficacy as a depressant, and may be given as an adjuvant to morphia, or morphia and tartar emetic, in cases of tetanus attended with a robust and plethoric state of the system. It lowers the action of the heart, promotes perspiration, and relieves spasm. Veratrum viride acts in a similar manner.

Camphor and assafœtida, administered in large doses, occasionally aid in controlling the spasms in this disease, but they should never be trusted in alone. Their influence, as antispasmodics, is far inferior to that of morphia and tartar emetic.

Indian hemp, soon after its first introduction into practice, received a large share of attention in the treatment of this disease, especially from the East India practitioners, some of whom were at one time disposed to regard it as a specific. Subsequent experience, however, has greatly disappointed these expectations, and in this country very little,

if any, confidence is placed in the remedy. I certainly have never derived any appreciable benefit from it in the few cases of tetanus in which I have employed it, although the trials in each were very fair. The preparation usually given is the extract, in doses varying from one to two grains, repeated every two hours, or even more frequently, the object being the production and maintenance of narcotism.

The Calabar bean has been repeatedly employed in the treatment of tetanus, and cases have been reported in which its use was apparently followed by a complete cure. Its virtues, however, have undoubtedly been greatly overrated, and in two cases in which I made trial of it no appreciable benefit whatever resulted. The best form of the medicine is the extract, given in doses of one grain every two, three, or four hours, according to the violence of the symptoms.

Professor Christopher Johnston, of Baltimore, has reported several cases of traumatic tetanus, treated successfully with hypodermic injections of conia. His formula consisted of two drops of conia with one of sulphuric acid in one drachm of water, of which fifteen drops were introduced every two hours, day and night. In two other cases, one caused by gangrene from frost-bite, and the other by syphilitic ulcers of the leg, although the attacks were fatal, the remedy exerted a powerful influence in controlling spasm and muscular rigidity. Successful results have also been ascribed to the exhibition of gelsemium, tobacco, nitrite of amyl, and bromide of potassium.

Chloroform, administered internally, or inhaled in the form of vapor, has been much employed in this disease, and cases said to have been successfully treated by it have been reported by different observers, but how far they were really relieved by it is not determined. It is, however, certain that it generally signally fails to cure, and that it is of use chiefly in assuaging pain and spasm.

Much comfort is often experienced from the use of the vapor bath in the treatment of tetanus; the steam should be conveyed, by means of a tube, from the spout of a tea-kettle, or other suitable apparatus, under the bedclothes, and may be advantageously medicated with laudanum, or laudanum and chloroform. The remedy possesses no curative agency.

In my own hands nothing has afforded so much relief in mitigating suffering and preventing pain and spasm as quinine, combined with morphia, and given in doses of three to five grains every three or four hours. Other practitioners have found it equally valuable in this respect. Chloral, administered more or less freely, often acts beneficially in promoting sleep and preventing spasm. Even a cure is occasionally, at least apparently, effected by this agent; I say apparently, because in most of the recorded cases it is difficult, if not impossible, to eliminate the effects of chloral from those of other remedies. Dr. John B. Roberts, in 1877, published a table of nineteen cases of traumatic tetanus, treated with hydrate of chloral, in the Pennsylvania Hospital, of which sixteen perished, and three recovered. The remedy deserves further trial in this disease.

Bloodletting and mercury, the latter carried to the effect of salivation, were at one time much vaunted on account of their supposed efficacy in the treatment of tetanus. They have, however, of late years, been entirely abandoned. The patient is certainly reduced sufficiently soon without venesection; and as to mercury, its use has occasionally, as stated elsewhere, been followed by the very disease which it was intended to cure, the saliva streaming at the time from the mouth in enormous quantities.

When much exhaustion exists, the use of brandy, wine, and a generous diet is indicated, along with quinine and other corroborants. Rectal alimentation must be employed when the patient is unable to swallow. The profuse and exhausting sweats so often attendant upon the disease are best controlled by atropia or atropia and aromatic sulphuric acid, and by frequent sponging of the surface with a strong solution of alum.

Whatever treatment may be adopted, proper attention should be paid to the bowels, which are generally excessively torpid, and, consequently, difficult to be moved. When the patient is in a condition to swallow, he may take ten grains of calomel, with double that quantity of jalap, every six hours, until there are free alvine evacuations. If the medicines are tardy in their action, the operation may be promoted by the addition of a drop of croton oil, or by means of a stimulating injection, as spirit of turpentine and castor oil. Occasionally, croton oil may advantageously be rubbed upon the abdomen. Severe purging must be carefully avoided, as, from its irritating and prostrating effects, it cannot fail to aggravate the complaint.

The treatment of tetanus by counterirritation is, in great degree, obsolete. It was formerly thought, when the disease was supposed to be essentially connected with inflammation of the cerebro-spinal axis, that extensive and rapid vesication of the spine would

afford valuable aid in combating the morbid action, and putting a stop to the spasms; and examples illustrative of the beneficial effects of this mode of treatment have been published by different observers. The remedy usually selected is either the common blister, hydrate of potassium, or the actual cautery. The late Dr. Hartshorne, of this city, was in the habit of employing a solution of hydrate of potassium, in the proportion of one drachm and a half to two fluidounces of distilled water. It produces a powerful rubefacient effect, and may be applied by means of a cloth mop to a narrow line of skin, from the occiput to the sacrum. If the hot iron be used, it should be applied transcurrently. I have, however, great doubts in regard to the propriety of any measures of this kind, believing that they frequently aggravate the symptoms instead of relieving them.

When the disease is chronic, and there is a wound which is still open, but indisposed to heal, the best plan is to divide the parts freely with the knife, so as to relieve them of engorgement, and invite a more salutary action. It is under such circumstances that the actual cautery occasionally answers a good purpose. In a case in the practice of Dr. W. D. Stewart, of Indiana, the particulars of which he has kindly communicated to me, an immediate stop was put to the paroxysms by this procedure, after various other means had been fruitlessly tried for nearly a fortnight. No spasms took place after the application, and the patient, a lad nine years of age, made a prompt and perfect recovery. The wound which had provoked the attack was a large lacerated one, occupying the right side of the scalp, and extending down to the bones.

Anodyne and stimulating liniments, strong veratria ointment, and ice-bags applied along the spine, have sometimes acted beneficially, both in moderating the spasms and in eradicating the disease. Chloroform has also been used a good deal in this manner, and cases of its successful employment have been reported; among others, a very interesting one, by Dr. Hinkle, of Pennsylvania, of a woman who suffered from tetanus from the bite of an eel. The treatment was conjoined with purgatives and antispasmodics, as cannabis Indica, valerian, and compound sulphuric ether.

Finally, if the patient be so fortunate as to survive the disease, the greatest care must be observed during his convalescence, lest relapse occur and destroy him, when he is apparently on the verge of returning health. The clothing should be warm, the diet light but nutritious, the bowels and secretions duly regulated, and exposure to atmospheric vicissitudes sedulously avoided.

After all that has been done by modern science for the cure of traumatic tetanus, the humiliating fact stares us in the face that, of the many remedies that have been paraded before the profession, there is not one that is worthy of special confidence. An analysis of the cases tabulated by Dr. Cowling clearly shows, as Professor Yandell very justly remarks, that the results of treatment by different remedies are so nearly alike that no one agent can properly be considered as possessing any decided superiority over any other. All, in fact, are equally of apocryphal virtue.

SECT. IV.—NEURALGIA.

Neuralgia is an affection of the nerves attended with severe, agonizing pain, often paroxysmal in its character, liable to occur in all parts of the body, and generally dependent upon some local irritation, or upon the joint agency of a local and constitutional cause. As it would be out of place in a work of this kind to treat of neuralgia in general, I shall limit my remarks here chiefly to the disease as it manifests itself in certain nerves, particularly those about the face, where the lesion not unfrequently becomes the subject of surgical interference.

The causes of neuralgia are various and of the most opposite character. They are predisposing and exciting. Persons of a nervous, irritable, or hysterical temperament are more prone to the disease than any other class of individuals. The gouty and rheumatic also frequently suffer from it. Depressing influences, whether mental or corporeal, are among its most common predisposing causes. Dyspepsia and anemia, by lowering the powers of the system, remarkably favor its development.

The disease occurs in both sexes, at all ages, and at all seasons; it is most common, however, from the twentieth to the fiftieth year, and in winter and spring, in cold northern regions, and in districts abounding in malarial exhalations. Cold and damp states of the atmosphere are especially favorable to its production. Like gout and rheumatism, the disease occasionally manifests a hereditary predisposition, and in a number of instances I have met with it in several members of the same family. No parts of the body are exempt from its attacks. It is particularly frequent in the head,

face, and jaws. The hysterical temperament disposes to neuralgia of the spine, joints, and bones.

The exciting causes of neuralgia are of a local and general nature. Among the former, exposure of a nerve to the air, or its compression by some tumor, as an exostosis, or soft growth, is the most common. The most atrocious attacks of this disease are generally witnessed in the branches of the trifacial nerve, in consequence of caries of the teeth, laying open their cavity, and thus allowing the air and other irritating substances to come in contact with the denuded nerve within. Similar effects are often produced by the pressure of a dental exostosis, or by the mere thickening of the periosteum covering the fang of a tooth. Occurrences of a like nature often excite neuralgia in the bones. Sometimes the disease is awakened by the contusion of a nerve, occasioned by a blow, fall, or kick; by the irritation of an old, indurated cicatrice; or by the excitement induced by the presence of a foreign body, as a splinter of wood. In the face, neuralgia may be caused by the lodgment of a piece of dead bone in the nose or antrum. A calculus may produce the disease in the bladder, worms in the bowels, and the larvæ of insects in the frontal sinus. Neuralgia of the pelvic viscera is often induced by the pressure of a displaced uterus upon the surrounding structures.

Exposure to cold while the body is overheated and covered with perspiration is a very common exciting cause of neuralgia. When the predisposition to the disease is very strong, the slightest draught of cold air will often almost instantaneously bring on an attack. Exposure to heat is less injurious, although it is also capable of exciting the disease, especially when the heat is concentrated for any length of time upon one particular locality.

Attacks of neuralgia are sometimes induced by gastro-intestinal irritation, dependent upon a redundancy of acid, indigestible food, worms, impacted feces, or an overloaded state of the bowels. The disease is not uncommon in dysmenorrhœa, in ulceration of the neck of the uterus, in spinal irritation, and in organic lesions of the brain.

A syphilitic taint of the system occasionally gives rise to it. Lancereaux has recorded three cases of sciatica which, having long resisted all treatment, yielded as if by enchantment to the use of mercury and iodide of potassium. Gonorrhœa may act in a similar manner, the attack being characterized by the suddenness of its invasion, the rapidity with which it attains its maximum of intensity, and the shortness of its duration.

Occasionally the cause is seated in the nerve itself, as when it is inflamed, partially ulcerated, or denuded of its natural coverings. After amputation, the stump often becomes affected with neuralgia in consequence of the extremities of some of the nerves being expanded into neuromatous tumors; and similar effects sometimes supervene upon the division of the nerves in cases of wounds, especially lacerated ones.

Finally, the occurrence of neuralgia, as a consequence of malaria, is familiar to every one. In the southern and southwestern States of the Union, where neuralgia of every form and grade is extremely prevalent, the disease, in the great majority of cases, recognizes no other cause. The attacks, under such circumstances, are generally of a distinctly intermittent type, very similar to those of intermittent fever, recurring once every day or every second day, and, after having continued with great severity for several hours, gradually going off, to reappear about the same period on the next day; each paroxysm being, perhaps, ushered in by chilly sensations, and terminating in more or less profuse perspiration.

Symptoms.—The nature of the pain in neuralgia is not always the same. In one case, it is dull, heavy, and aching; in another, acute and extremely violent; in a third, it resembles the pain produced by thrusting needles into the tissues; in a fourth, it is pungent, smarting, or burning; in a fifth, it is sharp and darting, like an electric shock, running through the parts with the rapidity of lightning.

The pain, whatever its character may be, is generally attended with more or less soreness and tenderness of the affected parts, which sometimes pit on pressure, although they are seldom discolored. Finally, the pain may be concentrated, or diffused; that is, it may be strictly localized, or limited to one particular spot, and that, perhaps, a very small one; or it may be extended over the greater portion of a nerve, or even over its entire length.

It is important to bear in mind that the pain often breaks out at a point very remote from the one upon which the impression provoking the attack is made. Thus, supraorbital neuralgia is often produced by disorder of the stomach, or of the stomach and bowels; a carious tooth has been known to give rise to neuralgia of the hip; and spinal irritation not unfrequently occasions neuralgia of the leg, heel, and foot. A very singular

case has been reported where a severe attack of neuralgia of the left forearm could always be instantly excited by touching the meatus of the right ear.

Neuralgia is sometimes associated with rheumatism, and it is to this form of the disease that the term rheumatico-neuralgic is usually applied by nosologists. The combination is most generally met with in persons of an arthritic predisposition, commonly affects the muscles, especially the intercostal and spinal, and is often exceedingly intractable, rendering the patient miserable for life, and at length wearing him out by the constancy of his pains.

Neuralgia often exists simultaneously in different parts of the body, and when it is once fairly established it is easily excited by the most trivial circumstances. Its progress is variable. In many cases it readily yields to treatment, or disappears even spontaneously; on the other hand, it is sometimes a most intractable disease, worrying and fretting the patient, undermining his general health, and disqualifying him for business and enjoyment. In its worst forms the suffering is almost constant; whereas, in the milder, there are not unfrequently long intervals of complete, or nearly complete, exemptions from pain. When the affection is contracted early in life, and proves rebellious, it is seldom entirely got rid of, whatever means may be adopted for its relief.

Pathology.—The pathology of neuralgia is not understood. It has generally been supposed to consist in a mere exaltation of the sensibility of the nervous tissue, but if this were true it would, probably, not be so intractable a disease as it often is. The explanation may, perhaps, hold good in those cases in which the disorder is very transient, or of malarial origin. In general, however, there is some degree of inflammation, either in the nerve-pulp or in the neurilemma, or in both, as is proved by the fact that the parts supplied by the affected nerves are commonly more or less tender, œdematous, and even somewhat discolored; phenomena clearly indicative of an engorged and incited state of the capillary vessels with a tendency to effusion. In other cases, again, it may consist in a mere perversion of the nervous fluid, as when a nerve is compressed by interstitial deposits, or by causes acting upon its periphery, thereby interrupting the current across the seat of the obstruction.

Neuralgia seldom proves fatal. Its course is irregular. It may last for months, years, a lifetime, the patient finally dying of some other disease. The most dangerous form is visceral neuralgia, which sometimes causes death by the constancy and violence of the attendant pains.

Treatment.—The treatment of neuralgia must be deduced, in great degree, from the nature of the exciting cause, which should, therefore, always receive prompt attention, removing it where this is practicable, or modifying it where it is not, so as to render it as harmless and inoperative as possible. In neuralgia of the face, for example, it will often be found that the cause of the trouble is a carious tooth, upon extracting which the pain instantly vanishes. Neuralgia dependent upon the presence of an old, callous cicatrice, can only be successfully relieved by the excision of the offending tissues. Vermifuge medicines are indicated when it is caused by worms; antacids, when it is excited by vitiated secretions of the stomach; purgatives, when it is occasioned by an overloaded state of the bowels. Thus, it will be perceived that no single remedy, or class of remedies, is adapted to all cases; a fact which strongly suggests, in every instance, the importance of a most thorough and critical examination of the state of the part and system, with a view to the institution of a rational therapeutics.

It must not be expected, however, that the disease will always disappear upon the removal of the exciting cause. Generally, indeed, it will, and that very promptly and effectually; but there are cases where it is inclined to linger, with little or no mitigation, for an indefinite period, the affected parts being seemingly unable to recover their natural functions, either because they have become habituated to the morbid action, or because they have experienced some organic change which no medication can reach.

The treatment of neuralgia is general and local, except when the cause is obviously of a purely local character, when general means may usually be dispensed with. Purgatives, a proper regulation of the diet, and antineuralgic remedies, as they are named, constitute the more important constitutional measures; while embrocations, leeches, vesicants, the hypodermic use of morphia, and section of the affected nerves, comprise the more efficient and reliable topical agents.

There are few cases of neuralgia which are not benefited by the use of purgatives; sometimes, indeed, the disease promptly disappears under a few brisk cathartics. Their exhibition is particularly indicated when there is a coated state of the tongue, disorder of the stomach, a vitiated condition of the secretions, headache, pain and aching in the limbs,

or an overloaded condition of the bowels. The best articles are blue mass, colocynth, and jalap, or the compound calomel pill, repeated every other night until there is a decided improvement in the general health. Emetics may often be advantageously exhibited, especially when there is evidence of biliary and gastric derangement. The pain is generally mitigated by their action, and sometimes completely removed, the moment they begin to manifest their specific effect.

The diet must be plain and simple, easy of digestion, and adapted, in regard to its nutritive qualities, to the exigencies of each particular case. The plethoric will be benefited by abstinence; the pale and anemic, by good living. When the general health is much impaired, tonics, as quinine and iron, a generous diet, wine, brandy, porter, and ale, with exercise in the open air, will be of service. Sometimes a sea voyage, or a residence near the sea shore, is salutary.

There are several articles of the materia medica which may be considered as exerting, in some degree, a specific influence over neuralgic affections, and which have hence received the name of antineuralgic remedies. To this class belong quinine, arsenic, strychnia, aconite, and morphia, along with some other anodynes, and the different preparations of iron.

Quinine, the great antiperiodic in intermittent fever, is entitled to the highest rank in the treatment of neuralgia, particularly in that variety in which the paroxysms observe a regular diurnal relapse, with an interval of entire freedom from suffering. It may be administered by itself or in union with an opiate, and a few efficient doses are almost sure to break up the attack promptly and effectually. In my own practice, I seldom give less than ten grains at a dose, repeated every six or eight hours, until the affection is either vanquished, or the specific effects of the medicine are rendered apparent by the aural and cephalic distress. Some practitioners prefer smaller doses, but experience has shown me that they are less trustworthy, and that, at all events, a much longer time elapses before they put a stop to the disease. Quinine is sometimes very beneficial when the affection is not of malarial origin, but, in general, its effects are much less apparent.

In chronic neuralgia, or in acute but obstinate attacks, arsenious acid is generally found to be one of the best remedies, given in doses varying from the eighth to the fifteenth of a grain, three times a day, in union with an anodyne, or anodyne and tonic. There are few cases of the disease, however obstinate, that will not be materially benefited by the use of this article, if administered with proper judgment and perseverance. The acid is far preferable, in every respect, as an antiperiodic, to Fowler's solution, as it is much less liable to cause nausea and anasarca.

With the value of strychnia, as an antineuralgic, every practitioner is familiar. I have used it, as such, for many years, and its effects have rarely entirely disappointed my expectations. The dose recommended in the books is much too large. I rarely give more than the sixteenth or twentieth of a grain, thrice in the twenty-four hours. Extract of nux vomica is also employed for the same purpose, but is seldom productive of any decided benefit.

In trigeminal neuralgia the most reliable remedies are croton chloral, gelsemium, and Duquesnel's crystallized aconitia. The first of these articles may be exhibited in one grain doses every hour. The gelsemium is administered in the form of tincture in doses of twenty drops every half hour until three doses have been taken. Aconitia is contra-indicated in disease of the heart. In ordinary cases the one hundred and fortieth of a grain, dissolved in alcohol, glycerine, and water, is repeated every eight hours.

In some cases relief is more readily obtained from the exhibition of chloride of ammonium than from any other remedy. It is particularly serviceable in neuralgia of the face and head, especially in that form of the disease known under the name of hemicrania; but it may also be very advantageously employed in neuralgia of the viscera, spine, chest, and extremities. The dose should generally be large, as from twenty to thirty grains, repeated three or four times in the twenty-four hours.

The use of morphia is absolutely indispensable in the treatment of neuralgic complaints, not so much as a curative agent, as for the purpose of controlling the excessive pain and inducing sleep. There are cases, however, which are radically cured by the persevering exhibition of this remedy, but then it is generally necessary to give it in large and sustained doses. Protracted narcotism has occasionally vanquished the disease after all other means have failed to afford even temporary relief. Several examples of this kind have fallen under my own immediate observation, and others have been mentioned to me by professional friends. For ordinary purposes the quantity need not exceed a fourth

or third of a grain, and, in chronic or subacute cases, I rarely give more than the tenth, twelfth, or fifteenth of a grain, repeated thrice a day.

For many years past I have been in the habit of employing, with very happy effects, in a great variety of cases of neuralgia, a combination of some or all of the above articles, giving them in pill form three or four times in the twenty-four hours. The subjoined will serve as a type of such a formula.[1] It need hardly be added that the effects of the prescription should be carefully watched, as several of the articles are of a potent and even a poisonous character. If the system be anemic, two grains of the sulphate of iron or of the valerianate of that salt may be incorporated with each pill. Carbonate of iron I never use, as it has always disappointed my expectations, even when administered in large doses and for a long time, and my experience, in this respect, is, I believe, fully corroborated by the results of the observations of other practitioners. When the attack depends upon the presence of a redundancy of vitiated gastric acid, the solution of valerianate of ammonium will be found a highly efficient remedy, administered in the dose of a drachm every two or three hours until relief is afforded. Iodide of potassium has been much lauded as an antineuralgic; but, although I have used it in many cases, I cannot recall to my mind a solitary one wherein it seemed to be really of any material service. If it ever does any good in this disease, it is when it partakes of a syphilitic nature.

When the attack is of a rheumatico-neuralgic type, colchicum will generally act more kindly and promptly than any other article. My invariable plan, however, is to give it in union with a full dose of morphia, as half a grain of the salt with one drachm of the wine of colchicum, every night at bedtime, which will be found to be a much better practice than administering these substances in smaller and more frequently repeated quantities.

The topical remedies which particularly claim attention on account of their real or imputed virtues are counterirritants, leeches, morphia, electricity, and the steam of hot water, either simple or medicated.

The only counterirritants that, in my judgment, are at all admissible, in the treatment of this disease, are blisters, ammonia, and iodine. Setons and issues are out of the question, except in deep-seated, obstinate visceral neuralgia, when the latter occasionally prove beneficial, especially if made with the hot iron, directly over the seat of the pain, so as to afford a free and protracted discharge. The moxa, formerly so much used, has of late years fallen into disrepute. Blisters are particularly valuable in inflammatory neuralgia; they should be retained until the epidermis is well raised, and they are the more desirable because the raw surface thus made may be advantageously employed for the topical application of morphia. Temporary relief, but nothing more, occasionally follows the use of ammonia in the form of liniment, or of Granville's lotion, frictions with ointment of veratria, and painting the parts with tincture of iodine. Leeching is sometimes useful, by relieving congestion, and thus removing one cause of compression of the nerve-pulp, the operation being performed as nearly as possible to the seat of the disease.

Professor Hammond speaks highly of the primary galvanic current, furnished by fifteen or twenty Smee's cells. The positive pole should be placed over the seat of pain, and the application should be continued for half an hour every day for several weeks.

Hot applications are generally beneficial in putting a prompt stop to the severity of the pain, especially if they are medicated with laudanum, or some other anodyne preparation. They may be used in the form of cloths wrung out of hot water, and covered with oiled silk, to prevent evaporation; or, in that of steam conveyed directly to the part by means of a tube connected with a tea-kettle placed over a spirit lamp near the bed.

Of all the local remedies for neuralgia, the most reliable, so far as my experience goes, at all events so far as transient relief is concerned, is the hypodermic injection of morphia, as nearly as possible to the seat of the pain. A good average quantity of the salt is from one-third to half a grain, dissolved in one drachm of tepid water, and introduced with a good syringe. In very urgent cases the quantity may be increased, and its value greatly enhanced by the addition of the fiftieth of a grain of sulphate of atrophia.

Another remedy of great value, strongly recommended by Professor C. G. Comegys, of Cincinnati, is the hypodermic injection of twenty to thirty drops of sulphuric ether,

[1] ℞ Quiniæ sulph. ʒj ;
    Morphiæ sulph. gr. jss ;
    Strychniæ sulph. gr. ij ;
    Acid. arseniosi gr. ij ;
    Ext. aconiti gr. xv.
Mix, and make xxx pills ; one to be given three or four times a day.

thrown into the affected tissues twice a day. The remedy has been found especially beneficial in sciatica.

Veratria ointment, prepared with from forty to sixty grains of the alkaloid to the ounce of simple cerate, is also an excellent remedy, from which I have frequently derived the very happiest effects. A small quantity—a portion about the size of a cherry—is applied two, three, or four times a day to the seat of the disease, with the bare fingers, the friction being continued until it produces a strong tingling, smarting, or burning sensation, when the surface is covered with wadding or soft flannel. In the milder forms of the disease veratria occasionally acts as a curative agent, although, in general, it is simply a palliative.

Mere division of a nerve for the cure of neuralgia is a perfectly useless procedure. Excision, on the contrary, is often followed by the happiest results, especially when performed for neuralgia of the face, caused by disease of the second and third branches of the fifth pair. Quite a number of very bold and novel operations have been performed within the last thirty years upon these nerves, especially the superior maxillary, by American surgeons, Professor Carnochan having led the way. The methods by which the object is accomplished will be fully described in their proper place. Sections of the larger nerves, as, for example, the sciatic, median, ulnar, and musculo-spiral, have sometimes been removed, and, indeed, even the brachial plexus itself, as in the examples recorded by Sands and Seguin, Maury, and others, although rarely with any permanent benefit. Occasionally, however, there is an exception to this rule, as in a case of neuralgia, consequent upon a gunshot wound of the median nerve, treated by Dr. J. L. Stewart, of Erie. The injury had been inflicted ten years previously, and the pain, which had been of the most atrocious character, requiring immense doses of morphia for its relief, was speedily and permanently cured by the excision of three inches of the affected nerve, without any unpleasant consequences in the parts naturally supplied by it.

Nerve-stretching, for the relief of neuralgia, has lately been attracting much attention, and from the success, partial or complete, which has attended it, is worthy of more extended trial. The operation consists, first, in exposing the affected nerve by a free incision ; secondly, in hooking it up, if large, with the index finger, or, if small, with an aneurism needle ; thirdly, in stretching it more or less thoroughly ; and, lastly, in replacing it in its natural locality, the wound being closed and treated in the usual manner. In a nerve like the sciatic, the patient's limb, after the stretching is effected, is lifted from the table by the nerve. The success of the operation is complete when the neuralgia is of traumatic origin.

SECT. V.—PARALYTIC AFFECTIONS.

1. WASTING PALSY.

A peculiar affection of the muscles, consisting essentially in atrophy and fatty degeneration of their fibres, has been described under the name of progressive muscular atrophy, or wasting palsy, from the fact that wasting and loss of power of these structures are its most prominent features. The disease, first accurately delineated by Cruveilhier, has been studied with great care by several European observers, especially Aran, Duchenne, Wachsmuth, Eisenmann, Meryon, Jackson, and Roberts.

Wasting palsy presents itself under two varieties of form, the partial and general ; the first, as the name implies, being limited to particular muscles, or sets of muscles ; whereas the other involves nearly all the voluntary muscles, those of mastication and those of the eyeball, including the elevator of the upper lid, being the only ones exempt from its ravages. The involuntary muscles, however, remain altogether intact, even in the worst cases and in the most advanced stages of the disease. Hence, the reason why the general health is usually so perfect amidst this wreck of the active agents of locomotion.

Of the causes of atrophy and palsy of the muscles nothing is positively known. If their development has occasionally been clearly traced to the effects of cold, to rheumatism, or to excessive and long-continued fatigue, such as attends various mechanical pursuits, it is equally certain that, in the great majority of instances, no plausible reason can be assigned for their occurrence. Now and then the lesion appears to have a syphilitic or strumous origin.

The time of life at which the disease occurs is variable ; it has been noticed in young children, and, on the other hand, occasionally in old subjects ; but the most obnoxious period would seem to be between twenty-five and thirty-five. Thus, in eighty-eight cases,

analyzed by Dr. Roberts, in 1858, the average period was thirty years and six months. General atrophy is not limited to any particular age, but attacks indiscriminately children, adults, and old persons; whereas the partial form rarely shows itself before puberty and after fifty. Both sexes are liable to it, but males suffer much oftener than females. The lesion has occasionally been observed in several members of the same family, and also in the offspring of persons who had themselves been its victims, thus exhibiting a kind of hereditary tendency.

The muscles that are most liable to suffer in this affection are those of the extremities, especially the upper. The wasting generally begins at one particular part of a limb, from which it gradually extends to another; but, now and then, cases are met with in which it attacks simultaneously several points.

It has been noticed that there is usually a tendency in certain muscles to suffer together, as if they were united by a very close fellow-feeling; thus, it has been found that whenever wasting palsy occurs in the muscles of the hand, it is extremely liable to affect those of the forearm also; a similar disposition has been remarked in reference to the muscles of the shoulder and those of the arm. Moreover, experience has shown that when one limb is invaded, its fellow is very apt to share the same fate.

The most important *symptoms* of this disease are wasting of the muscles and loss of contractile power, generally coming on in a slow, gradual, and stealthy manner. In the great majority of cases, indeed, the person is unconscious of the mischief that is taking place, until attention is accidentally directed to the subject by a failure of the power of one of his limbs, especially the hand and foot. "The tailor discovers," says Dr. Roberts, "that he cannot hold his needle; the shoemaker wonders he cannot thrust his awl; the mason finds his hammer, formerly a plaything in his hand, now too heavy for his utmost strength; the gentleman feels an awkwardness in handling his pen, in pulling out his pocket handkerchief, or in putting on his hat. One man discovered his ailment in thrusting on a horse's collar; another, a sportsman, in bringing the fowling-piece to his shoulder." The wasting, at first very slight, progressively increases until the affected muscles are rendered perfectly soft and flaccid, and their substance is so much wasted that they are hardly one-fifth of the natural bulk; they are, in fact, completely withered, as if they had been starved, and deprived of all nervous influence. The loss of power is generally in proportion to the wasted condition of the muscles, proceeding gradually from bad to worse, until the parts are entirely disabled and useless, no effort of the will being capable of exciting the slightest action.

Besides the above more prominent symptoms, there are others of a minor and subsidiary character. These are fibrillary tremors, cramps and twitches, pain, and a remarkable susceptibility to cold.

Fibrillary tremors, or convulsive twitchings, are very common, especially in the earlier stages of the complaint; they are dependent upon the irregular contraction of individual muscular fibres, and are, consequently, always absent when the disease has reached its full development. They generally occur without the consciousness of the patient, and may usually be readily excited by exposure of the affected parts to a current of cold air or water. Cramps are also very frequent; they come on at various intervals, and often constitute a source of actual suffering, especially when they are accompanied with pain, which is present in about one-fourth of the cases. The pain may be slight and wandering, severe and fixed, or sharp and neuralgic, shooting about in different directions with the rapidity of lightning. In some instances it occurs in different parts of the muscular system, more or less remote from the seat of the disease, and is then apparently of a rheumatic character. Wasting palsy causes a remarkable sensibility to cold, especially to a cold, humid atmosphere, so that the patient requires an uncommon amount of clothing to keep himself warm and comfortable. Finally, the galvanic excitability of the muscles regularly diminishes with their decay, although it is not wholly annihilated until they have completely lost their primitive structure.

It is remarkable that, amidst all this wear and ruin of the muscular system, the general health should uniformly remain unimpaired, even in the worst forms of the disease. The appetite and sleep are excellent; digestion is well performed; the bowels move with their accustomed regularity; and the functions of the kidneys are perfectly normal. The intellect is clear to the last, and the senses retain their wonted vigor. The only trouble which the patient occasionally experiences is difficulty of respiration, from involvement of the diaphragm.

The progress of the disease is generally slow, the muscles steadily decaying, until they are at length completely changed in their character; for months and even years they

retain some contractile power, and are even susceptible of restoration. General atrophy is always a gradual affection; it seemingly begins in the partial form of the lesion, and is probably merely an aggravated state of it. When the disease has reached this crisis, the patient may be unable to use any of the muscles, excepting, as already mentioned, those of mastication and those of the eye.

The appearances revealed on *dissection* are characteristic. The muscles, as might be expected, are wasted in various degrees; some slightly, others very much, and others, again, so completely as to be hardly recognizable, consisting merely of fibrous vestiges, with no distinct trace of the normal structure. The color of those that still remain is much faded, being pale red, rose, buff, or yellowish, according to the extent of the atrophy; and in all, or nearly all, there are well-marked evidences of granular and fatty degeneration, the former generally preceding the latter, although they occasionally exist independently of each other. Sometimes these changes are confined to one particular part of the muscle, as one-half or two-thirds of its belly, while the other portion retains its natural hue and consistence. Under the microscope, the striped primitive fibres are observed to have vanished, their place being supplied by granular matter and oil globules, and their investing tunic broken down and disintegrated.

The nervous system has been closely scrutinized during the past few years in many of the reported cases of wasting palsy, and it appears to be well established that the affection depends upon chronic inflammation of the gray substance of the anterior tract of the spinal cord, with secondary atrophy of the anterior roots of the nerves derived from the seat of the lesion.

The prognosis is generally unfavorable; the partial form is occasionally recovered from, the complete never. In the latter case death, which does not occur under several years, is usually preceded by great difficulty of respiration, in a paroxysm of which the patient suddenly expires. In partial atrophy, the disabled muscles, after having struggled on for many months, perhaps neither sensibly advancing nor receding, gradually awake from their torpor, and ultimately regain some contractile power, although never their full vigor.

In the *treatment* of wasting palsy, any disorder of the general health should promptly be corrected. If the lesion can be clearly traced to a syphilitic or strumous taint of the system, as is occasionally the case, the proper treatment will be iodide of potassium with bichloride of mercury; or, when a tonic effect is required, potassium with iodide of iron. Gentle purgatives will be useful when there is constipation with derangement of the secretions. The diet must be plain, simple, and unirritant.

The best local remedy, in the early stage of the disease, is a blister sufficiently large to cover the whole of the affected muscles, and retained long enough to produce thorough vesication. If decided improvement do not follow in a week or ten days, the application should be repeated. The hot douche, immediately followed by the cold, will also be found serviceable, but to prove efficacious it should be aided by frictions with some stimulating embrocation, as spirit of camphor, or alcohol and ammonia. Veratria ointment is a powerful excitant, and has frequently proved highly efficacious in my hands. The cold douche alone is objectionable, on account of its depressing tendencies. Massage will be found useful, and should be practised several times a day. Galvanism has been greatly extolled by Duchenne, Meyer, Gros, and others, and there can be no doubt that it has occasionally rendered good service. The constant primary current should be passed rapidly over the disabled muscles, taking care to return to each several times during the same sitting; it should be strong in proportion to the obtuseness of the parts, but be gradually diminished as the sensibility augments, otherwise overstimulation may occur, and thus do harm instead of good. The application may be repeated, at first, every twenty-four hours, and afterwards twice a day.

The treatment, whatever it may be, should be combined with gentle exercise of the affected parts, to recall them, as it were, to a sense of their duty. They should, in fact, be reëducated by a system of careful training, steadily and perseveringly continued for many months, if not for several years. Conducted in this way, great confidence may be entertained of ultimate benefit.

2. INFANTILE PALSY.

There is a variety of paralysis which, occurring in young children, generally during the first dentition, is, in point of obstinacy and incurableness, if possible, still more deplorable than the one above described. It may be called infantile palsy. Its attacks are usually sudden and unaccountable. The child goes to bed in the evening, perhaps to all

appearances perfectly well; during the night, however, he becomes feverish and restless, and in the morning, on attempting to walk, he is unable to stand or use his legs. The limbs soon lose their round, plump appearance, the muscles are rendered soft and flaccid, the feet trail the floor, and the surface feels cold and numb, although sensibility is seldom entirely destroyed in any case, however extensive.

The seizure is much more common in the lower extremities than in the upper; very often it is confined to one thigh and one leg, or to one thigh or one leg alone; but occasionally both limbs, or even all four, are involved, the child being perfectly helpless, and in the most pitiable condition. The paralysis is generally complete, but cases occur in which the little sufferer is still able to use certain muscles, although not with anything at all like their natural freedom and strength. When the upper extremity is attacked, the deltoid muscle is very liable to be affected, becoming remarkably soft and wasted, so that the patient finds it impossible to elevate the arm or lift the smallest weight.

The cause of this variety of palsy is not always very evident. In general, however, it depends upon inflammation of the anterior horns of gray matter of the spinal cord, followed by atrophy and disappearance of the nerve cells. As the result of these central changes, the muscles usually undergo fatty degeneration, and the development of the bones is arrested.

The general health is seldom impaired in infantile palsy; the mind acts with its accustomed vigor, and all the bodily functions are well executed. As the child advances in years, all the limbs, excepting the disabled ones, increase in size and strength, but the latter remain stationary, or dwindle away still further, and thus form a striking contrast with the sound. In cases of long standing, there is often fatty degeneration of the muscles, although occasionally the paralysis continues for years without any change of this kind.

The prognosis is variable, although generally unfavorable, especially if the disease is neglected or improperly managed in the first instance. Little, if any, benefit will be likely to accrue from any mode of treatment, however judiciously or perseveringly conducted, after the lapse of six, eight, or ten months. The difficulty of effecting restoration is much increased when there is fatty degeneration of the muscles; a circumstance which may readily be ascertained by extracting, by means of a small trocar, devised by Duchenne, and delineated at page 433, a minute portion of the suspected structure, and subjecting it to a microscopical examination. The absence of electric contractility is also an unfavorable sign. If the induced current is powerless, the cure will be difficult, while it will be impossible if the muscles do not respond to the galvanic current.

The *treatment* of infantile palsy must mainly be directed, in the first instance, to the spinal cord, upon the disorder of which the disease essentially depends. For this purpose, leeching, cupping, rubefacients, and blistering, with absolute rest in the recumbent posture, should promptly be employed, soon followed, if the case is likely to be obstinate, by a free issue with the actual cautery, applied as nearly as possible to the seat of the lesion. The discharge must not be too abundant, or protracted, otherwise it may occasion undue debility. Frictions with veratria ointment along the whole length of the spine and of the sciatic nerve, repeated twice in the twenty-four hours, have been of great service in my hands. An early resort to mercury is very important. The best form is calomel, in doses of the fourth of a grain, night and morning, continued, with an occasional brief intermission, for several successive months. The fluid extract of ergot is also indicated in the early stage of the disease, or before atrophy of the muscles has set in. In some instances, especially in the more chronic forms of the disease, I have derived signal benefit from a combination of iodide of potassium and bichloride of mercury. As recovery advances, strychnia may be of use, but I have never seen any good from its exhibition in the earlier stages of the complaint. When the child is feeble and anemic, iron and quinine, milk punch, and fresh air must be conjoined with other means to invigorate the system. The bowels and secretions must receive proper attention.

The affected extremities must frequently be rubbed, shampooed, switched, and placed upon a course of careful training, as advised under the head of wasting palsy. Immersion of the limbs in water as hot as it can be borne, for twenty to thirty minutes, twice in the twenty-four hours, will be found to exert a highly beneficial influence in restoring temperature. The early and long-continued application of electricity is often followed by great improvement, if not positive relief, and should never be neglected. The alternate use of faradization and galvanization will probably insure the best results.

The contraction of the tendons, consequent upon this variety of palsy, must be rectified by appropriate apparatus, aided, in obstinate cases, by tenotomy.

3. PSEUDO-HYPERTROPHIC MUSCULAR PARALYSIS.

A distinct form of paralysis, first observed and accurately described by Duchenne, in 1858, and consisting essentially in hypertrophy and sclerosis of the interfibrillar muscular connective tissue, is occasionally met with in infancy and early childhood, and is known as the pseudo-hypertrophic or myo-sclerosic paralysis, or progressive muscular sclerosis.

The disease generally begins before the tenth year, mostly in boys, without any assignable cause, but now and then after convulsions. As soon as the child begins to walk, weakness of the lower limbs, with inability to stand or move without stumbling, is noticed, and is soon followed by a peculiar, stiff, waddling gait, the limbs being separated from each other, and the body rolling from side to side. The spine is curved forwards in the dorso-lumbar region, the belly being prominent and the shoulders thrown backwards, thereby producing the characteristic attitude of the affection, which is due to debility of the extensor muscles of the trunk, and disappears during recumbency. In the course of a few weeks or months the muscles of the calves become enormously hypertrophied, and, while those of the thighs, buttocks, and loins are soon involved, the muscles of the upper extremities are less commonly affected. With the advance of these changes, the paralysis is more strongly marked, the gait is more uncertain and tottering, and the child becomes finally utterly helpless. The circulation of the affected limbs is lessened, the skin being cold and mottled, but its sensibility is not impaired, and reflex and electro-muscular contractility are also decidedly diminished. Double equinus, or equino-varus, is not of infrequent occurrence.

The progress of muscular sclerosis is generally slow, the disease rarely terminating before five or six years from its commencement. As the paralysis advances, emaciation and impairment of the intellectual powers set in, and death results either from pulmonary complications induced by weakness of the respiratory muscles, or from some intercurrent disease.

Of the intimate nature of this variety of palsy nothing very definite is known, but it is probable that the anterior tract of gray matter of the cord is the seat of the morbid changes. The muscular fibres themselves are atrophied and non-striated, but otherwise unchanged; while the interstitial connective tissue is greatly hypertrophied, and, in the later stages of the affection, replaced by fat cells.

The treatment of this affection does not differ from that of ordinary infantile palsy, but all measures generally prove unavailing. Duchenne obtained one cure in thirteen cases by the induced current and shampooing, but the gastrocnemial muscles were only slightly enlarged, and Benedikt noticed marked improvement in three cases from the constant current to the lower cervical sympathetic ganglion and the lumbar region.

4. PARTIAL PALSY.

Besides the above forms of palsy there are some others, to which the term partial, transient, or anomalous may be applied, such, for instance, as loss of motion of one side of the face, one eyelid, one side of the tongue, or of the hand, forearm, arm, or shoulder, or even of the entire superior extremity. The subjoined facts will serve as illustrations of its character.

Pressure upon the nerves is liable to be followed by interruption of their functions, at one time temporary, at another permanent. A case recently came under my observation in which a man, thirty-five years of age, suffered from partial palsy of the forearm and hand from having rested for two hours with his head upon the limb as he lay asleep upon the floor.

In another case, under my notice several years ago, temporary paralysis of the left upper extremity was produced by the arm, thrown across the top of a chair, being compressed by the head while the man was asleep. Pressure of the head of a crutch upon the axillary plexus of nerves occasionally leads to weakness, numbness, and pricking pain in the arm, hand, and fingers. Recently a youth of fifteen was under my charge on account of paralysis of the arm, consequent upon a fall on the shoulder from a railway car, two months previously. The limb was instantly deprived of motion and sensation, and so continued up to the time of his visit. The head of the humerus had been thrown slightly forwards against the coracoid process, but it exerted no perceptible pressure upon the brachial plexus of nerves.

Paralysis of one side of the face from injury of the portio dura is not infrequent ; more generally the affection is caused by suppression of the cutaneous perspiration, from exposure to cold and wet ; and an instance is occasionally met with in which it is produced by disease of the petrous portion of the temporal bone. The subjoined case affords a good illustration of a very common form of facial palsy. A blacksmith, eighteen years of age, of temperate habits, came under my care on account of paralysis of the left side of the face. The attack had occurred suddenly three days previously, without any apparent cause, soon after eating a moderately hearty dinner. He had been subject to frequent and severe paroxysms of headache, preceded by dizziness and vertigo. On the morning, however, on which he was seized with palsy he had felt uncommonly well. His appetite and sleep had always been good, and his bowels regular. The palsy was characterized by loss of motion in the muscles of the left side of the face, and by inability to close the left eyelids, accompanied with a want of sensibility of the skin. The tongue, when protruded, inclined to the right side, and was deprived of feeling and taste, a lump of sugar, held in the mouth, making no impression on the affected side of the organ. The general health was excellent.

In the treatment of these paralytic affections, special attention must be directed to the improvement of the general health, which is often seriously impaired, by the use of laxatives, alteratives, and a properly regulated diet. In obstinate cases, a mild mercurial course is sometimes serviceable, especially when the lesion is dependent upon organic disease of the brain, or of the cerebro-spinal axis. The principal local remedies are leeches, blisters, stimulating embrocations, veratria ointment, and the hot and cold douches, followed by dry friction. Occasionally electricity proves beneficial.

CHAPTER IV.

DISEASES OF THE LYMPHATIC VESSELS AND GLANDS.

The pathologist can certainly not boast of his knowledge of the diseases of the lymphatic vessels ; he knows, it is true, that they are liable to inflammation, but of the manner in which it is produced, and of the effects to which it gives rise, he is, in great measure, ignorant. That these vessels play an important part in various affections is extremely probable ; but such are their excessive tenuity and the great delicacy of their structure that no one has yet been able to point out the character and amount of their participation. It has been supposed that at least one form of cutaneous disease, namely, erysipelas, essentially consists in inflammation of the absorbents, and it must be confessed that the opinion, although insusceptible of demonstration, is highly plausible. Much light has, however, been thrown upon the injuries and diseases of the absorbent system, by the writings of Dr. S. C. Busey, of Washington, which may be profitably consulted by the reader.

SECT. I.—LYMPHATIC VESSELS.

Inflammation of these vessels, technically called angeioleucitis or lymphangitis, is most advantageously studied in connection with external injuries, particularly punctured and poisoned wounds, of which it is by no means an infrequent consequence. Doubtless, the disease is sometimes idiopathic, or dependent upon internal causes, such as give rise to erysipelas and other bad forms of inflammation in the cutaneous and other tissues. In the case of a gentleman recently under my observation, the disease, which involved both upper extremities, was evidently due to disorder of the digestive apparatus, occasioned by malaria. Three similar attacks had been experienced before, each coming on during the latter part of August, and promptly yielding to quinine. Numerous superficial vessels were involved in each of the attacks. When arising as a consequence of an abrasion, or the prick of a needle, as in sewing up a dead body, the affected vessels can be easily

traced, as they pass beneath the skin, as small, reddish cords, tense. nodulated, and painful to the touch, accompanying the principal veins, and extending as far as the nearest glands, in which they appear to terminate. The number of these reddish lines is variable; sometimes there are only two or three, while at other times there are as many as six, ten, or a dozen, forming a kind of band, from half an inch to an inch in width. Whenever the number is considerable, there is always a good deal of concomitant swelling; and the parts, feeling stiff, sore, and tender, readily pit on pressure, owing to the effusion of sero-plastic matter. In the more severe attacks of angeioleucitis, as those consequent upon inoculation with putrid or poisonous matter, the tumefaction soon becomes general, spreading rapidly over the whole limb, and the discoloration, losing its striated appearance, so characteristic of the disease in its earlier stages, also assumes a diffused disposition. Arrived at this point, it is usually impossible to distinguish this affection from ordinary erysipelas, so closely do the two lesions resemble each other.

Occasionally the inflammation seems to take its rise in the deeper layers of vessels, and then the discoloration is generally preceded by considerable induration of the subcutaneous connective tissue, giving the part a kind of brawny sensation; by and by, however, red streaks appear in the skin, and then the disease follows very much the same course as when it begins in the superficial vessels.

However originating, the affection nearly always involves the neighboring lymphatic glands, causing them to enlarge, and to become tender, red, and painful. In some of the worst forms of angeioleucitis, the glands manifest signs of being diseased before the absorbents themselves are apparently implicated. Such an occurrence, although uncommon, is occasionally met with in inflammation of these vessels consequent upon dissection wounds.

Angeioleucitis no doubt sometimes passes into suppuration, and, perhaps, even into gangrene; but of these occurrences, as pure, uncomplicated affections, our knowledge is too imperfect to justify any positive opinion.

The symptoms ushering in an attack of angeioleucitis are usually such as are denotive of constitutional depression, following pretty closely upon the injury sustained by the affected vessels. The patient, after having felt indisposed for some hours, seldom more than from twelve to twenty-four, is seized with chilly sensations, accompanied with flushes of heat, a disposition to yawn, headache, pain in different parts of the body, and a dry and contracted state of the skin. Sometimes the attack is announced by violent rigors, rapidly succeeded by high fever and delirium. If the local affection is at all severe, the symptoms soon assume a typhoid character, the pulse becoming weak and frequent, the surface hot and dry, and the tongue covered with a brownish fur. The local distress, meanwhile, increasing, abscesses form in different portions of the limb, the matter being of a foul, unhealthy character, and disposed to spread extensively among the surrounding-structures, in the same manner as in erysipelas and other bad forms of inflammation.

Angeioleucitis may be confounded with other diseases, particularly erysipelas and phlebitis, and the distinction is by no means always so easy as might at first sight appear. In fact, it can only be made out satisfactorily in the earlier stages of the complaint, the principal source of diagnosis being the red, striated appearance of the affected surface, reaching from the seat of the injury up to the nearest lymphatic glands. In phlebitis, the discoloration is also linear, but the cords are much larger, firmer, more knotty, and more deeply seated; they are also less numerous, and there is not nearly so much involvement of the lymphatic glands. In erysipelas, the inflammation usually begins as a circumscribed affection, with diffuse, uniform redness, not striated, as in angeioleucitis, or in phlebitis.

In the *treatment* of this disease, the same general principles are to be observed as in erysipelas and phlebitis, to which it bears so close a resemblance. The exciting cause being removed, such local and general means are to be employed as may seem to be best adapted to the exigencies of each particular case. Bearing in mind that, if the disease is at all severe, the symptoms will be likely soon to assume a typhoid character, the surgeon will take care not to deplete much, especially with the lancet and purgatives, lest he be instrumental in inducing fatal exhaustion, of which the danger may be already sufficiently great in consequence of the progress of the morbid action. Leeches may be applied along the course of the affected vessels, but not directly over them, if the disease is in its earlier stages, and the patient is robust and in the prime of life. They should be employed in considerable numbers, and be succeeded by warm fomentation, the whole limb being

enveloped in flannel cloths wrung out of a strong solution of acetate of lead and opium, and kept constantly wet. The application of iodine is sometimes advantageous; and good effects occasionally arise from thorough vesication, the blister being stretched along the course of the affected vessels. If matter form, or great tension and throbbing exist, suitable incisions must be made.

The constitutional treatment must be regulated by the character of the general symptoms. Purgatives, to clear out the bowels and correct the secretions; iron, or iron and quinine, to improve the tone of the system and the state of the blood; and anodynes, to allay pain and induce sleep, with a properly regulated diet, will constitute the most reliable and efficient means. If marked debility arise, brandy, wine, or porter, with nutritious broths, will be required. When the disease proves obstinate, or becomes chronic, a mild mercurial course may be beneficial.

Varicose enlargement of the lymphatic vessels, or lymphangiectasis, has occasionally been noticed, chiefly among the inhabitants of warm countries. It is most common in the vessels of the scrotum and lower extremity, in union with elephantiasis. The enlargement is sometimes so great and so well defined as to give rise to distinct swellings, which have been described by Virchow and other pathologists, under the name of lymphangioma. In a case mentioned by Carswell, in a young man, twenty-six years of age, a tumor nearly as large as an orange existed in each groin, for which he had worn a double truss from his boyhood, under the supposition that he had hernia. On dissection, however, each tumor was found to consist of enormously dilated absorbent vessels connected with the inguinal glands. When cut into, instead of presenting a solid, compact structure, it had the appearance of a coarse sponge, most of the vessels being from one to three lines in diameter. The same phenomenon was witnessed, only in a more striking degree, in the lymphatics of the pelvic and lumbar regions. The spongy and elastic character of such a swelling ought to prevent any serious error of diagnosis. Hardly any treatment would be necessary in such a case. Excision might prove dangerous, and should not be practised without due deliberation. Bean has reported three cases in which he effected a cure by establishing adhesive inflammation by means of the seton.

In *wounds* of these vessels there is occasionally a veritable *lymphorrhœa*, or a discharge of thin, pale, whitish fluid, standing like drops of sweat upon the affected surface. The exudation has been known to continue for a considerable length of time, and to interfere perplexingly with the healing process. Vidal and Lebert have each described a case in which small, transparent vesicles, filled with lactescent fluid, formed upon the thigh and scrotum. In the case detailed by the latter, the vesicles, after having attained a certain bulk, broke, and discharged their contents, which, on analysis, were found to contain sugar of milk and minute clots. The patient, aged twenty-one years, was affected with hypertrophy of the scrotum.

In the case of a boy, nineteen years of age, affected with elephantiasis of the lower extremity, Dr. J. C. Morris, of the Episcopal Hospital of this city, observed, two weeks after his admission, several vesicles on the thigh, which soon gave exit to lymph, which flowed at the rate of nearly a pint in twelve hours. This continued for five days, when it ceased, apparently in consequence of an attack of erysipelas. In a case of Desjardins eleven pounds escaped in the course of forty-eight hours. At the clinic of the University of Padua, in the summer of 1868, Professor Vanzetti was kind enough to show me a man who had suffered in this way for five years in the left side of an hypertrophied scrotum, large quantities of fluid being discharged every few days.

A wound with such a discharge may, if it heal slowly, at length degenerate into a troublesome *fistule*, difficult to cure, and the seat of a constant exudation of milky fluid, mixed with pus. A similiar accident occasionally follows upon an abscess situated in the course of a large lymphatic trunk. The remedies most likely to afford relief in such cases are systematic compression and the application of the solid nitrate of silver. If these fail, recourse should be had to the knife, Vienna paste, or the actual cautery.

A congenital lymph fistule is sometimes met with, especially in front of the neck. It has generally a very small, almost imperceptible, orifice, and is the seat of a transparent, limpid discharge, possessing all the properties of ordinary lymph. The discharge usually occurs in drops, and may, with occasional intermissions, continue for years. The treatment is similar to that of the accidental lymph fistule.

SECT. II.—LYMPHATIC GLANDS.

The lymphatic glands are liable to inflammation, chronic enlargement or hypertrophy, lymphoma, sarcoma, tubercle, and earthy degeneration.

Inflammation of these bodies, technically called adenitis, may show itself either as an acute or a chronic affection, and is of such remarkable frequency as to demand special consideration. In whatever form it occurs, it is most common in young children of a strumous predisposition, and is generally brought on by attacks of cold, or by some local irritation implicating the afferent lymphatic vessels. The disease, moreover, may be common or specific, of the latter of which illustrations are afforded in syphilitic bubo, in the bubo of plague, and in the swelling of the lymphatic glands of the axilla consequent upon dissection wounds and malignant pustule.

1. *Acute adenitis* is most common in the glands of the neck, jaw, and supraclavicular region ; it is also occasionally met with in those of the groin and axilla. The disease may be limited to one of these bodies, or, as is more generally the case, affect a considerable number of them ; beginning as a hard, painful knot, exquisitely tender to the touch, and rapidly augmenting in bulk, until, in some instances, it attains the volume of an almond or a pullet's egg. The increase in the size of the tumor is sometimes exceedingly rapid, as is often seen in adenitis of the neck from exposure to cold, where a body of this kind, scarcely perceptible in the natural state, may, in the course of a few hours, acquire the size of a filbert, or a small marble. As the disease advances, the swelling extends to the adjacent connective tissue, the skin becomes red and inflamed, and the parts pit on pressure. The discoloration is not unfrequently of an erysipelatous character. When the inflammation is fully developed, the local distress is usually very severe, and the constitution actively sympathizes with the suffering textures, the patient being feverish, deprived of appetite and sleep, and affected with constipation.

Dissection shows the affected glands to be of a deep reddish or brownish color, infiltrated with sero-plastic fluid, softened, lacerable, or easily crushed with the finger ; the connective tissue around is also abnormally vascular and infiltrated, and, in many cases, it seems to be the principal seat of the morbid action.

Adenitis may end in delitescence or resolution, pass into suppuration or assume a chronic character. The occurrence of gangrene is very uncommon.

The disease sometimes vanishes in a few hours, either spontaneously, or under mild treatment. Enlarged and inflamed glands of the neck, and at the angle of the jaw, often rapidly disappear under frictions with ammoniated liniment, conjoined with the use of hot drinks and immersion of the feet in hot water. When the inflammation is more severe, an active purgative will be necessary, followed by a gentle diaphoretic, as one-fourth of a grain of morphia with one-half that quantity of tartar emetic. The diet must be light, and the part and system must be kept perfectly at rest. If the morbid action threaten to prove troublesome, or to pass into suppuration, leeches and medicated fomentations must be employed. In many cases, dilute tincture of iodine will be very beneficial in cutting short the disease.

When adenitis passes into suppuration, matter generally begins to form from the fifth to the tenth day, the event being usually most rapidly excited in young, weakly, or scrofulous children, with an impoverished state of the blood. The pus is not always situated in the enlarged glands ; in many cases, in fact, it is limited, in great degree, if not entirely, to the neighboring connective tissue. It is of a light yellowish color verging on greenish, thick, and often very copious ; occasionally it is mixed with blood, and with the débris of the affected glands. Finally, the matter may occur as an infiltration, or as a distinct abscess. The microscopical characters of pus from a lymphatic gland are seen in fig. 263.

Fig. 263.

Scrofulous Pus from a Lymphatic Gland. $\frac{250}{1}$

The occurrence of suppuration is announced by increased heat, pain, redness, and swelling, along with a sense of throbbing, and by high constitutional disturbance, attended by chilly feelings, or even rigors, followed by fever and perspiration.

The treatment is strictly antiphlogistic. If the phenomena are clearly denotive of the existence of pus, an early incision is made, free and dependent, to favor thorough evacuation and prevention of reaccumulation. The operation is followed by warm water-dressing or an emollient cataplasm. The use of a tent or drainage tube will occasionally be required to maintain patency of the puncture.

In regions of the body which are habitually exposed, as, for instance, the neck, and

where, consequently, it is of great importance to avoid unseemly scars, the best plan generally is to evacuate the pus by a series of small punctures, succeeded immediately by gentle pressure, the operation being repeated every two or three days until the matter ceases to form. Some surgeons, with the same end in view, use the aspirator, but I am not aware that the method possesses any advantage over the ordinary operation.

2. *Chronic adenitis* is a very common occurence, generally as a consequence of the acute form of the disease, but sometimes it is, apparently, a primitive affection. However this may be, its effect is gradually to subvert the natural structures through increased thickness of the reticulum and diminution in the number of the lymph cells, as in fig. 264, from Green. In the earlier stages of the disease, the gland is of a reddish, brownish, mottled hue, considerably increased in size, and of a firm, fleshy consistence; by and by, however, it assumes a grayish or whitish aspect, becoming almost homogeneous, and cutting very much like an unripe apple or pear; in some cases it is very soft and lacerable. When the transformation is very great, the hardness of the gland may be equal to that of scirrhus, with which it is then liable to be confounded. A distinct capsule, composed of dense connective tissue, generally surrounds the enlarged body, which is capable, in this condition, of attaining the volume of a small orange. When a number of such glands are agglomerated together, a large tumor is formed, of a hard, firm consistence, more or less adherent to the neighboring parts, and of an irregularly lobulated appearance, as in fig. 265, copied from one of my preparations.
Fig. 264.

Chronic Inflammation of a Lymphatic Gland. $\frac{200}{1}$

Chronically enlarged or hypertrophied lymphatic glands are most commonly met with in the neck, or about the lower jaw. In the internal cavities they are most frequently seen in the mesentery and pelvis, and at the root of the lungs. The effect which these bodies exert upon the structures among which they are situated is principally of a mechanical character, compressing them, and so interfering more or less with the exercise of their functions. Thus, in the neck they may cause injurious compression on the trachea, vessels, and nerves; in the pelvis they may interfere with parturition by preventing the descent of the child's head; while in the lungs they may occasion suffocation by obstructing the entrance of air into the bronchial tubes.

Various causes may give rise to this affection; some of a local, others of a purely constitutional nature. In the neck, it is often occasioned by cold, or by disease of the jaw, teeth, gum, or tonsil; in the groin, by ulceration of the penis; in the axilla, by disorder of the mammary gland; in the mesentery, by irritation of the small bowel. The most efficient general cause is a strumous state of the system; but there is reason to believe that the lesion may be produced by anything that has a tendency to derange the general health, or to impoverish the fluids and solids.

Fig. 265.

Hypertrophied Lymphatic Glands.

Chronic enlargement of the lymphatic glands often continues for years, now advancing, then stationary, and now, perhaps, receding; in general, however, the disease is obstinate, especially when the structure of these bodies has undergone serious organic changes, in which case it is often extremely difficult, if not impossible, to reclaim them by any mode of medication, however perseveringly or judiciously employed.

The *treatment* of chronic adenitis is both constitutional and local. In the first place, the exciting cause is looked for, and, if possible, removed; the carious tooth is extracted, the ulcer on the penis healed. The general health is improved by attention to the bowels and secretions, and by strict hygienic observances. When plethora exists, detraction of blood, and antimonial and saline preparations, will be of service; under opposite circumstances, the proper remedies will be a nutritious diet, and alterant tonics, consisting of iodide of iron and quinine, bichloride of mercury, iodide of potassium, and cod-liver oil. When there is no contraindication, minute doses of mercury in

Huxham's tincture of bark will often be highly efficacious, but care should be taken not to carry it to decided ptyalism. Tartar emetic also, given in small doses, as the tenth or twelfth of a grain, three times a day, is frequently very beneficial. In most cases a regular system of purgation should be maintained. The German practitioners are fond in this disease of the use of chloride of ammonium, administered in doses of five to ten grains three times in the twenty-four hours. The article is a powerful sorbefacient, and is, therefore, worthy of trial, especially in cases which do not yield to the more ordinary measures. Quinine has often yielded excellent results in my hands.

Among the more important topical remedies are leeches, and sorbefacient liniments, unguents, and embrocations, conjoined with systematic and steady compression. These means must be employed with great caution and judgment, otherwise they will be sure to be productive of harm instead of benefit. All sorbefacient applications should, in the first instance, be of a mild character, their strength being gradually increased as the parts become more tolerant of their impression, and their peculiar effects are rendered more and more apparent. Of these one of the best is composed of one part of iodoform to two parts of balsam of Peru, and five of cosmoline. When the enlarged glands are favorably situated, compression will often be found to be a most valuable remedy, applied with the pad of a truss, as in hypertrophy of the inguinal glands, or with a compress and bandage when it affects the glands of the neck. In obstinate cases, a blister occasionally exerts a salutary influence, relieving the enlarged structures of engorgement, and stimulating the absorbent vessels so as to induce them to remove morbid deposits. The electric current has sometimes been advantageously used. Subcutaneous division of the enlarged glands, or comminution with the bistoury, has occasionally been practised, but the effects, at least in my hands, have not been such as to render a repetition of the operation at all desirable.

Finally, when the disease is intractable, the only resource is removal of the morbid mass, provided it be favorably situated for such a procedure. Such a step, however, should not be lightly taken, as it must often involve serious consequences, on account of the great depth of the tumor, and its connection with important structures. In the cervical region, for example, the excision of a mass of enlarged and indurated lymphatic glands not unfrequently proves a most difficult, embarrassing, bloody, and hazardous operation. Removal will be much facilitated if the knife be kept close to the hypertrophied glands. Sometimes the enlarged and disintegrated structures may be pressed out bodily through a small opening in the skin. When the diseased mass compresses the trachea or great vessels of the neck, and does not admit of removal, relief must be sought by the subcutaneous section of some of the constricting muscles, especially the sternocleido-mastoid.

3. The lymphatic glands are occasionally the seat of hyperplastic formations, termed *lymphomas*, or lymphadenomas, which, in their minute structure, consist essentially of a very delicate, reticulated stroma, inclosing lymph corpuscles in greatly increased numbers. The general features of this growth have been so fully described at page 218 that the merest reference here must suffice.

4. *Sarcomatous tumors* of the lymphatic glands are characterized by proliferation of the cells of the trabeculæ, with atrophy and final disappearance of the lymph follicles. Lymphosarcoma differs from ordinary lymphoma in the following particulars, the clinical features of the two affections being so distinct that a mistake in the diagnosis is scarcely possible. Commencing usually as a single tumor, it is not circumscribed by a capsule, but is diffused through the surrounding tissues, sparing neither the muscles, the bloodvessels, the sheaths of nerves, nor the adjacent lymphatic glands. Its growth is progressive and very rapid, enormous dimensions being attained in a short time, and, as it advances, it contracts adhesions with the skin, which becomes discolored and, finally, ulcerated. If extirpated, it is almost certain to return, and secondary deposits occur early in the lungs, liver, spleen, and skin. The dissemination may often be traced to embolism, the mass adhering to and perforating the walls of the large venous trunks, and permitting the detachment of small fragments, which are carried to distant organs by the blood.

In 1871, I removed a growth of this description, of the size of a large fist, from the neck of a gentleman, twenty-eight years of age. It was first noticed two years previously, and, after having attained the volume of a small orange, it remained stationary until six months before the operation, when, suddenly and without assignable cause, it took on renewed action. It was lobulated and elastic; the skin was discolored and closely adherent, and, on account of its deep and important connections, the dissection was tedious. Death occurred, apparently from cellulitis, on the tenth day. On micro-

scopical examination, the neoplasm was found to be composed of closely-packed, small, round cells, with large nuclei and bright nucleoli, the intercellular substance being sparse and homogeneous.

5. *Tubercular* disease of these bodies, as stated in the chapter on scrofula, is met with chiefly in young subjects, before and soon after the age of puberty; most generally in children. Now and then it occurs in elderly persons, but this is very uncommon. Surgically considered, it is most frequent in the glands of the neck and jaw, and may be limited to one of these bodies, or, as is most generally the case, affect a large number, either simultaneously or successively. It often coexists with tubercular disease of the lungs, joints, and other parts. The proper remedy, when the disease is not too far advanced, is excision with a view to prevent infection of other organs.
Fig. 266.

Cretaceous Degeneration of the Lymphatic Glands.

6. The lymphatic glands occasionally undergo *earthy degeneration*, as in fig. 266, being converted into a soft, whitish substance, not unlike chalk. Such an occurrence is most common in the bronchial and mesenteric glands, but is also sometimes seen in those of the neck. Not long ago I met with a case in which not less than five of the cervical glands had become completely calcified, being of stone-like solidity, of a light brownish color, rounded, and from the size of a pea to that of a hazelnut. The patient was a middle-aged, strumous woman, and the glands, forming a chain along the inner edge of the sterno-cleido-mastoid muscle, on the right side, had been affected from early youth. Their character was obvious on the slightest touch. Excision was easily effected. Such tumors need not be interfered with, unless they are a source of annoyance by their situation.

CHAPTER V.

DISEASES AND INJURIES OF THE ARTERIES.

SECT. I.—WOUNDS AND HEMORRHAGE.

THERE can be no more terrible and appalling sight to a patient and his friends than hemorrhage from a divided artery, especially when the blood is gushing out in a full and angry torrent, threatening every moment to put an end to existence. There is something indescribably sickening and distressing in such a scene, from which every sensitive mind shrinks with dismay and bewilderment. The horror of the scene is increased a hundred-fold when we are unable to afford the requisite relief. But the sight of blood is not disagreeable only to the common observer; there are few surgeons, however heroic or well disciplined, who do not, at times, participate in this feeling. If it were not for the frightful hemorrhage which so frequently attends them, operations would be divested of nearly all their terror, and few men would shrink from their performance. Fortunately or unfortunately, however—for it is not easy to determine which—this is not the case; the slightest incision is often followed by profuse bleeding, and in the extirpation of tumors, in the removal of limbs, and in various other procedures, the patient has reason, in many cases, to congratulate himself if he do not perish from the loss of blood. Some of the more serious accidents, as incised, gunshot, and punctured wounds, often prove instantly fatal from hemorrhage; or, if syncope should, luckily, ensue, and thus temporarily arrest the bleeding, death may occur subsequently, but not less certainly, from the same cause. It is for these reasons that hemorrhage has always been a source of so much anxiety to the surgeon, and that its study has engaged so large a share of his attention from the earliest stages of medical science down to the present time. It is, indeed, impossible for him to be too well acquainted with the subject, or too thoroughly prepared to meet its various, trying and painful emergencies. The reflection, which must often arise under such circumstances, that possibly all was not done that might have been done if greater skill had been exercised, is well calculated to overwhelm the sensitive and conscientious surgeon, and to induce a degree of distress which no one, who had not himself experienced it, can possibly appreciate. I do not envy the feelings of that man who, through ignorance,

inattention, or indecision, allows his patient to perish from loss of blood when he ought to save him.

The characteristics of arterial hemorrhage are, first, the scarlet color of the blood, and, secondly, the peculiar manner in which it issues from the injured vessel; it spirts out in jets, synchronously with the contraction of the left ventricle, and not in a steady, continuous stream, as when it comes from a vein. This, however, is true only of the larger arteries; for, when the smaller branches are severed, their contents escape very much like those of a vein, only more forcibly, the fluid even then often projecting to a distance of several feet. When one of the principal trunks is divided, the blood is frequently sent with great violence to the ceiling, or far across the room, to the horror and dismay of every one present. It is worthy of note that arterial blood in a person partially asphyxiated, or fully under the influence of an anæsthetic, is of a dark color, like that of venous blood. The effects of hemorrhage vary very much, and are not by any means always in proportion to the extent of the injury. When proceeding from a large artery, or a considerable number of small ones, it may prove almost instantly fatal, or, at all events, in a few minutes. In general, however, the case does not progress so rapidly. The patient, after the bleeding has continued for some time, is seized with syncope, and now, the heart's action being greatly depressed, an opportunity is afforded for the formation of a clot both within and around the artery, followed by an arrest of hemorrhage. By degrees reaction takes place, color returns to the cheek, the extremities become warm, and the pulse reappears at the wrist. With these phenomena recurs the danger of bleeding. As the heart's action augments, the blood is again vigorously propelled through the body, and, presently, the temporary clot being washed away, the wound is reopened nearly, if not quite, to its original extent. Again fainting occurs, a new plug is formed, and for a time life is once more free from immediate risk; but this truce, like the first, is of short duration; the same scene is reënacted a second and a third time, until at last, by the repeated drain, the heart and the brain are no longer capable of supporting each other in the fearful struggle, and the patient sinks completely exhausted.

A person dying from repeated losses of blood, consequent upon the division of a large vessel, presents a fearful picture. His countenance is ghastly pale; his pupils are widely dilated; he pants and sighs for breath; his ideas are vague and confused; he is sick at the stomach, and vomits; the extremities are icy cold; and the whole surface is covered with a profuse, clammy perspiration. The thirst is usually intense and unquenchable, the largest quantity of water failing to satisfy the urgent wants of the system; excessive restlessness and jactitation succeed; the patient calls loudly for cold air; paroxysm after paroxysm of swooning recurs; the pulse has, perhaps, already been long absent from the wrist; the eyes assume a glazed and fixed expression; the respiration grows more and more feeble; and death often steals on so imperceptibly as to render it difficult to determine the precise moment of its occurrence. During all this time, whether it embraces only a few minutes or hours, or whether it extends through several days, there is generally an entire absence of pain, the loss of blood operating as an anæsthetic.

The reaction which follows upon copious loss of blood is generally attended with high excitement, known as "hemorrhagic fever." The symptoms which characterize it are peculiar. The blood, the natural stimulus of the heart, is utterly inadequate for the wants of the system, and hence, to send a certain supply to the more important viscera, especially the brain and lungs, as well as to its own substance, the organ is obliged to make extraordinary efforts, as is shown by the tumultuous nature of its action. The pulse is unusually soft and frequent, and accompanied with a peculiar jerking, vibratory sensation, distinguished as the hemorrhagic pulse, the skin is hot and dry, the countenance is slightly flushed, the eyes are suffused, the thirst and restlessness are intense, distressing noises are complained of, the head aches, and the temples throb and feel as if they were constricted by a cord. Nausea and vomiting are often present; the sleep is imperfect, and the mind not unfrequently wanders. If prompt relief be not afforded, the patient may perish from effusion of serum into the arachnoid sac and into the pleuritic cavities. The most suitable remedies are perfect rest of mind and body, cold applications to the head, frequent sponging of the body with tepid water, and full doses of morphia in union with the neutral mixture. Beef essence, chicken broth, and milk punch constitute the most appropriate diet. As soon as the condition of the stomach will admit of it, iron and ergot, or ergot and acetate of lead, should be freely given to increase the plasticity of the blood. If, during the progress of the case, the brain and lungs are threatened, the main reliance must be upon blisters and dry cupping, with, perhaps, in the former case, a few leeches to each temple. Light and noise must, of course, be excluded from the apartment.

When the hemorrhage has been excessive, as indicated by the pallor of the countenance, the feebleness of the pulse, and the gasping character of the breathing, transfusion of blood, as a dernier resort, should be employed. The operation, if not performed too late, is very encouraging, the statistics of Landois affording not less than 65 recoveries out of 99 cases, more than one-third of the fatal cases being moribund at the time.

Fig. 267.
Plan of Wounded Arteries. *a.* A mere Longitudinal Slit, extending to an oval space. *b.* A Similar Wound, in an Oblique Direction, gaping more. *c.* A less Wound transverse, with the proportional gaping great. *d.* A Transverse Wound of the same size at *a* and *b*, causing a very wide hiatus.

Wounds.—If we inquire into the nature of wounds of the arteries, it will be found that they do not differ, as it respects the weapons with which they are inflicted, from wounds in other tissues. Thus, they may be incised, punctured, lacerated, contused, or gunshot, and it would frequently be difficult to determine which class is the worst, or the most certainly and speedily fatal. In regard to their size they present every possible gradation, from the slightest incision to the complete division of the vessel; the wound being either oblique or transverse in the latter case, but of various shapes when the lesion is partial. Occasionally the wound consists of a mere vertical fissure. The different appearances here alluded to are all well displayed in fig. 267. The extent and character of the wound necessarily exert great influence upon the amount and duration of the hemorrhage, and, therefore, demand careful study.

When an artery has been completely cut across, there is an instantaneous and impetuous flow of blood, followed immediately by the retraction and contraction of each end of

Fig. 268.

Contraction of a Divided Artery. *a.* The Orifice of a Dead Artery. *b.* The Orifice of a Living Vessel immediately after Section.

Fig. 269.

Plan of Natural Hemostatics, in a Cut Artery. At *a*, the Cut End of the Arterial Tube; Conical by Contraction. At *b*, the Arterial Sheath Vacated by the Retracted Artery, and Occupied by Coagulated Blood. At *c*, the Coagulum Projecting from the Orifice of the Sheath.

the vessel, as exhibited in fig. 268. The effect of this double action is to diminish the amount and force of the stream, but not to arrest it; instead of this, it usually continues until a coagulum has formed upon the orifice of the artery, as well as in the parts immediately around, particularly in the loose connective tissue constituting its sheath. In this manner a mechanical obstacle is opposed to the effusion of blood, but this would soon be washed away if it were not aided and fortified by the speedy development of a coagulum within the vessel, extending usually as high up as the first large collateral branch. These clots, of which the first bears the name of external, and the other that of internal, fig. 269, are the means which nature employs to put a stop to the hemorrhage; not, however, until, as a general rule, it has proceeded to the extent of syncope, a circumstance always eminently favorable to the coagulation of the blood, and, consequently, also to the formation of the clots now described. But these clots, at this stage of the process, are necessarily very soft, as well as very imperfectly adherent; hence, in order to guard against their detachment, or, what is tantamount to this, against a recurrence of the hemorrhage, it is indispensable that these parts—clots, vessel, and surrounding structures—should become effectually and permanently soldered together. This accordingly soon happens; for within a few hours after the occurrence of the injury inflammation is enkindled, both in the divided artery and in its sheath, and this is followed by the proliferation of the endothelial cells of the internal coat and of the fixed cells of the sheath, and their extension into the clots, and the appearance of

colorless blood corpuscles, which are partly resident in the clots, and partly intruders from without. This new cellular tissue fixes the clots, and is subsequently transformed into connective tissue; and vessels finally show themselves, some of them being of new formation, while others, and perhaps the greater number, are derived from the divided artery and its sheath, as well as from the surrounding structures.

The two clots now described are, it will be seen, inseparably blended at the orifice of the divided vessel, and their form and arrangement may not inaptly be compared to a glass stopper, closely fitted into the neck of a decanter. The outer clot is rough and irregular, whereas the internal is perfectly smooth and cylindrical, except its cardiac extremity, which is nearly always conical. The longer the internal coagulum is the less danger will there generally be of its premature detachment.

Fig. 270.

The changes above mentioned as occurring in the two clots are generally the work of time; the gluing process is usually effected rapidly, since its function is to protect the patient against hemorrhage; but the removal of the serum and coloring matter of the blood, and the conversion of this fluid into solid matter, take place more slowly, and are often not completed under several months. Finally, if the parts be examined at a still later period, it will be found that both clots have entirely disappeared, and that the injured vessel, as high up as the first large collateral branch, has been transformed into a dense, strong, fibrous cord, fig. 270, similar to that observed in the umbilical arteries of the infant.

Such, then, is the process which nature employs for arresting the flow of blood from a divided artery. Taking advantage of the exhausted condition of the system consequent upon the shock and loss of blood, she instinctively forms the two clots, having, first of all, drawn away the vessel from the main wound, as well as caused it to diminish its caliber, and then she goes deliberately to work to fasten these clots at points precisely where they are most needed for the purpose. The ves-

Change in the Shape and Structure of an Artery after Ligation.

sel being thus hermetically sealed, she afterwards busies herself still further in getting rid of these plugs, as they now are no longer required, and, finally, completes the labor by converting the obsolete extremity of the artery into an analogous tissue. These changes, so profoundly curious and interesting, bear, it will be perceived, a very close resemblance to those which take place in the callus of a broken bone.

After the ligation of an artery, the supply of blood in the parts beyond the seat of the obstruction is maintained by what is called the collateral circulation, the vessel above communicating freely with that below, as in fig. 271, by its anastomosing branches.

Fig. 271.

Diagram of Collateral Circulation.

When an artery is divided only partially, whether transversely, obliquely, or longitudinally, an external clot forms, but this is generally so imperfect as to render it incapable of opposing an effectual barrier to the flow of blood. The edges of the wound, however small, have a constant disposition to gape; and hence, although plastic matter may, perhaps, be deposited in great abundance, yet it is impossible for the parts to contract permanent and satisfactory adhesions to each other. As soon as the circulation regains any of its natural vigor, the blood as it sweeps along washes off the clot, and appears upon the exterior of the wound; and thus the hemorrhage usually continues, paroxysm after paroxysm recurring in more or less rapid succession, until it proves fatal.

Although such is the course usually pursued when an artery is only partially divided, experience has shown that a spontaneous cure does occasionally take place. Such an event, which, however, at best is extremely uncommon, is most likely to occur when the opening is longitudinal; when the wound in the overlying structures is a mere fissure or canal, offering an imperfect outlet to the contents of the vessel; when the system remains for a long time in a prostrate condition; and when, finally, there is a very rapid and abundant deposit of plasma in the various tissues involved in the lesion, serving to glue them speedily and firmly together. That an incised wound, however, of considerable size, is sometimes healed in this manner, is proved by what occasionally happens when the brachial artery is injured at the bend of the arm in venesection.

Punctured wounds of the arteries are dangerous or otherwise, according to their size and the size of the affected vessel. If a pin be thrust into a large artery of an animal, and immediately withdrawn, a drop of blood exudes, but there is no further bleeding, the aperture being promptly closed by the natural elasticity of the coats of the vessel. Whether a similar effect follows such an occurrence in the human subject is not positively determined. Mr. Guthrie mentions a case in which fatal hemorrhage was produced by wounds of the carotid artery inflicted by pins; and he refers to two instances in which a similar result was witnessed from a puncture of the femoral artery made with a tenaculum. On the other hand, it is a well-known fact that acupuncture needles have repeatedly been inserted into the largest arteries with perfect impunity. It is very probable that an instrument of small size will produce different effects, so far as hemorrhage is concerned, in a denuded artery and in an artery that retains its natural relations, the blood, owing to the difference in the atmospheric pressure, being more readily forced out in the former than in the latter. However this may be, it is a matter of paramount importance, in performing operations upon the arteries, to avoid even the most delicate puncture, since such an accident might be followed by ulceration, and serious, if not fatal, hemorrhage.

Wounds inflicted by small shot partake of the nature of punctured wounds. In two cases of this kind under my charge, one involving the subclavian and the other the femoral artery, the openings made by the shot were found to be perfectly closed in less than three weeks after the accident. In gunshot wounds the hemorrhage is usually copious, if not speedily fatal, whether the artery, especially if it be one of large size, be partially or completely divided. When the coats are badly contused, or bruised and lacerated, as when they are grazed by the missile, secondary hemorrhage may be expected from ulceration or gangrene.

When the outer and middle coats of an artery are dissected off to a slight extent in an animal, no bleeding takes place, because the current of blood is not sufficiently strong to rupture the inner tunic; but such an occurrence in the human subject is fraught with great danger, as it is almost inevitably followed by fatal hemorrhage. A case recorded by Mr. Guthrie strikingly illustrates this fact. A man cut his throat with a razor, the instrument inflicting a transverse wound upon the carotid artery, but did not penetrate beyond the middle coat. The vessel gave way at the point of injury on the eighth day, and the patient died of hemorrhage. When an artery is nicked with a knife or forceps, as occasionally happens in the extirpation of a tumor with unusually firm and extensive adhesions, safety demands that the vessel should immediately be secured with the ligature. When the internal and middle tunics are divided, as in case of accident, the external, if severely injured, will be very liable to be assailed by ulceration; whereas, if it retain its integrity, the probability is that it will be gradually expanded into an aneurismal pouch, the more especially if it has undergone the atheromatous or calcareous degeneration.

Contused and lacerated wounds of the arteries generally bleed much less freely than incised and punctured. Occasionally, indeed, there is no hemorrhage whatever, even when the largest arteries are involved in the injury, and their denuded extremities are hanging loosely on the exposed tissues. In some instances the hemorrhage is momentarily profuse, and then ceases permanently; in other cases it continues, and proves speedily fatal. The reason why there is generally so little blood lost in injuries of this description is, as is fully explained in the chapter on wounds, that the ragged and paralyzed coats of the artery readily intercept the blood, and that the blood itself, in lesions involving the separation of an entire limb or the rupture of the larger vessels and nerves, always coagulates much more promptly and firmly than in ordinary incised wounds, the shock sustained by the system being highly conducive to the occurrence. Sometimes an effectual barrier is opposed to the effusion of blood in a ruptured artery by the sheath being drawn forward over its mouth, in the form of a hood.

When an artery is severely contused in its continuity, the resulting inflammation may be so great as to cause complete occlusion of the vessel at the seat of the injury, the blood coagulating as it sweeps over the affected surface, and the clot becoming firmly adherent through an abundant effusion of lymph. Or, instead of this, ulceration or gangrene may occur, and the patient may die of hemorrhage, as not unfrequently happens after gunshot injuries, the bleeding usually coming on within the first eight or ten days after the infliction of the wound.

But, although nature may, and, indeed, sometimes does, arrest the hemorrhage from a divided artery, yet no sensible surgeon would intrust her with such an office, when it is in his power to get at the seat of the wound ; for it is hardly possible to conceive of a case involving one of the larger trunks where her efforts would be likely to be successful, or where, if ultimately triumphant, the patient would not be brought repeatedly at death's door before she could attain her end. It is only in wounds of the internal arteries, as those of the chest and abdomen, and in the aorta and its larger branches, that we must refrain from direct interference, and limit ourselves to the use of general means calculated to keep down vascular action, especially the liberal use of anodynes and sedatives, as opium, aconite, and acetate of lead, the application of ice over the seat of the injury, exposure of the patient to cold air, and perfect quietude of mind and body. All active exertion must for a long time be avoided, in order that, if a cure should take place, the wound may not be suddenly reopened by the giving way of its edges, in consequence of the imperfect organization of the clots and of the plasma.

Treatment.—The means employed by art for suppressing hemorrhage are quite numerous, as well as greatly diversified in their nature, and will, therefore, require to be considered somewhat in detail. The most important of these means are : first, ligation ; secondly, acupressure ; thirdly, compression ; fourthly, torsion ; fifthly, forced flexion ; and, sixthly, styptics. Besides these, there are several others of a subordinate character, meriting merely a passing notice.

1. *Ligation.*—Ligatures are composed of various materials, as silk, linen, and soft leather. Of these, the first is the most unexceptionable, and almost the only one now employed. It should be round, smooth, well twisted, colorless, and so strong as not to break without considerable effort. For the smaller arteries, as the radial, tibial, and temporal, common sewing silk is well adapted ; but for the larger trunks, as the femoral, iliac, and carotid, stay silk, a much stouter article, is required. Some practitioners prefer what is called dentist's silk, no matter what may be the size of the vessel, on the ground that it is much stronger in proportion to its thickness than any similar substance, and, therefore, less liable to excite undue irritation. This thread, which is employed in making fishing lines, is rendered very hard and stiff by means of gum, which, however, is easily removed by boiling it for a few minutes in a slightly alkaline solution. Treated in this manner, a piece long enough to tie the iliac artery will hardly weigh the twenty-fifth of a grain. Hemp or linen thread makes an excellent ligature ; and, in case of emergency, a sensible surgeon will not hesitate to take anything that may be in his way. Whatever substance be employed, it is very important that it should be thoroughly waxed, otherwise it will be difficult, if not impracticable, to draw and tie it with a requisite degree of firmness, to say nothing of the greater tendency of the knot to slip. From eight to ten inches is a good average length for a ligature.

Animal ligatures were first introduced to the notice of the profession by Dr. Physick, early in the present century, and they have ever since been occasionally employed by different practitioners, chiefly American. The late Dr. Jameson, of Baltimore, used them nearly altogether for many years, under the belief, founded upon numerous experiments and clinical observations, that they were decidedly superior to all others, their presence never causing any of the irritation which so often follows the application of the ordinary substances. The article to which he gave the preference was soft buckskin leather, cut into thin, narrow strings, not tied too firmly, lest they should break, and be thus prematurely detached. Ligatures made of the fibrous elastic coat of the aorta of large animals have been introduced by Mr. Barlow. Dr. Ishiguro, of the Japanese army, strongly recommends the use of ligatures prepared from the tendon of the whale ; they are sufficiently strong to bear heavy pressure, do not cause irritation, and, although they are readily absorbed, they retain their hold long enough to prevent secondary hemorrhage. Mr. Croft, in 1881, tied the external iliac artery with a ligature made of the tendon of the kangaroo, and found great reason to be satisfied with the result. Other practitioners recommend catgut, or ligatures manufactured from the small intestine of the sheep, and others, again, the fibres of the sinew of the deer, the latter having been found to be particularly useful

by Professor Eve ; while the former, rendered antiseptic by immersion in a weak solution of carbolic acid, has been highly lauded by Mr. Lister. The advantage of the animal ligature is that, besides approaching more nearly to the living tissues than any other material, the ends may be cut off close to the knot ; its disadvantage, as formerly prepared, is that it soon becomes softened and disintegrated, from the imbibition of fluids, thereby rendering it liable to separate before it has accomplished the object for which it was applied. This objection, however, is overcome by steeping the catgut for two weeks in chromicized glycerine, a process by which it is greatly strengthened, drying it, and afterwards storing it in a one-to-five solution of carbolic acid and glycerine. Dr. Macewen, of Glasgow, has found that the best mixture for rendering the substance capable of resisting the action of the tissues for a fortnight is made by adding one part of a one-to-five watery solution of chromic acid to five of glycerine. For arteries of large size, the violin string, " E, No. 70," answers an excellent purpose. Prepared in the above manner, I believe that the catgut ligature is less liable than the ordinary ligature to be followed by suppuration, ulceration, and secondary hemorrhage ; and I have, therefore, no hesitation in giving it my entire approval. It is now fully ascertained that the carbolized catgut ligature is generally entirely absorbed within a few weeks after its application, and that its action on the coats of the artery is similar to that of hemp or silk, with the important exception that the outer tunic is not ulcerated. Dr. G. F. Arnaud recently tied the carotid or femoral artery fourteen times in dogs, which were afterwards killed at periods varying from four to sixteen days. In nine cases the ligature had entirely disappeared ; in two it was partially absorbed ; and in three it was little altered. In twelve of the cases the inner and middle tunics were divided, or the middle alone. The clot, when not absorbed, was very small, and the obliteration of the vessel was complete and firm. Pure raw silk is at present being employed as a substitute for catgut, but with what success remains to be determined.

Of late years the attention of surgeons in this country has been repeatedly directed to the use of metallic ligatures for tying arteries. The innocuous character of lead, gold, silver, and platinum wire, thus employed, was fully established by Dr. Henry S. Levert, of Mobile, in a series of experiments which he performed in 1828, and an account of which was published in the fourth volume of the American Journal of the Medical Sciences. The results proved not only that the inflammation consequent upon the operation was generally comparatively slight, but that in nearly every instance the metallic thread became speedily encysted, and might, if it had not been purposely removed, have remained for an indefinite period as a harmless tenant in the parts. Dr. Stone, of New Orleans, in 1859, tied the common iliac artery with a silver wire, and I soon afterwards secured the femoral in a similar manner. Since then I have adopted the procedure in a number of cases, and on two occasions I have left a metallic ligature permanently around the spermatic cord after extirpation of the testicle. In 1866, Dr. C. H. Mastin successfully tied the external iliac artery with silver wire, and in the same year I performed a similar operation upon the same vessel with equally good results. A number of other examples, of later date, might be cited, but this is unnecessary, as the safety and value of the operation are fully established.

Fig. 272.

Toothed Artery-forceps.

The wounded artery may be very conveniently drawn out with a pair of toothed forceps, fig. 272, with a tenaculum, fig. 273, or, what generally answers the purpose exceedingly well, an ordinary pair of pocket forceps. If the vessel is small, it should be seized in its longitudinal axis, but in the horizontal if it is large, since it is more easy in this way to occlude its orifice, and prevent the flow of blood. It is for this reason, also, that the forceps are generally to be preferred to the tenaculum ; the latter instrument,

Fig. 273.

Tenaculum.

however, possesses an advantage over the former when the artery is cut off very closely, or when it is desired to include some of the surrounding tissues. Care must be taken not to transfix the coats of the vessels, and then tie the ligature below the point of perfora-

tion, as this might lead to secondary hemorrhage. When no good assistant is at hand, the artery-forceps, delineated in fig. 274, an instrument with broad, serrated extremities, and a movable slide or catch, to close the blades, will be found convenient.

Fig. 274.

Sliding-forceps.

Dr. Prince, of Illinois, has devised a contrivance for seizing arteries, called the tenaculum-forceps, represented in fig. 275. As the names implies, it combines the advantages

Fig. 275.
Prince's Tenaculum-forceps.

of the two instruments, and may be applied with great efficiency to all arteries of medium size, as the blades are sufficiently wide to effect complete occlusion of their caliber.

The vessel being pulled gently out, as in fig. 276, is carefully isolated from its connections, either with another pair of forceps, the finger, or the knife, or all three together, as may be most expedient. The propriety of excluding from the ligature the smallest nervous filament, as well as the most insignificant vein, and every particle of muscular tissue, is too obvious to require any comment. Such a proceeding is absolutely necessary, not only to prevent pain and suppuration, but to promote the separation of the ligature. It is only when the vessel is very small that any of the tissues in which it is embedded should be included in the ligature. The ligature is applied to a sound portion of the artery, immediately above the instrument, and tied into a single knot, when it is drawn so firmly as to divide the inner and middle tunics, as in fig. 277, if the artery is large, or

Fig. 276. Fig. 277.
Mode of Drawing Out and Isolating an Artery.
Effects of Ligation upon the
Inner Coats of the Artery.

even of medium caliber; while, in the smaller branches, mere contact of the opposite surfaces is aimed at. In executing this part of the operation, the extremities of the ligature should be wound around the fore and middle fingers of each hand, while the thumb is extended upon them nearly as far over as the vessel, in order that the force may be exerted as gently and equably as possible. Nothing is more unseemly, or more truly reprehensible, in a surgeon or his assistant, than to pull a ligature by fits and jerks,

or so violently as to break it, or, perhaps, lacerate and tear off the artery itself. With a little care and gentleness, a comparatively weak ligature may be thrown around a vessel so as to answer the intention most fully. I dwell upon this point with some degree of emphasis, because it has happened to me to witness a very unusual number of these Herculean feats with the ligature, the men often pulling as if they had hold of a rope and piece of wood, instead of a delicate thread and artery. Fig. 278 shows the indented appearance of the artery after ligation.

The tying is completed with a double knot, when one end is cut off close, and the other brought out at the nearest angle of the wound. The knot which is thus made is the reef-knot, fig. 279, in which the ends of the thread lie across the artery, as in the lips of the wound in the ordinary interrupted suture. The surgeon's knot, fig. 280, is no longer used for the purpose, as, from the manner of making it, it is very irregular, and, consequently, ill adapted to the object. In tying very small vessels, sometimes only one knot is employed.

The practice of cutting off both ends of the ligature, and of closing the wound over the injured vessel, first suggested, towards the latter part of the last century, by Mr. Haire, of England, and subsequently so warmly lauded by Mr. Lawrence and Mr. Hennen, is

Fig. 278.   Fig. 279.   Fig. 280.

Reef-knot.   Surgeon's Knot.

Exterior of an Artery after ligation.
now universally abandoned, and very justly so, on the ground that the noose, after having performed its duty, creates irritation among the parts with which it lies in contact, leading thus to the development of abscesses, which continue to discharge so long as the foreign substance remains. When the ordinary animal ligature is used, this objection does not obtain, as the noose is soon removed by absorption, and a similar remark is applicable to the carbolized catgut ligature, which, when properly prepared, retains its hold sufficiently long to effect obliteration of the vessel without exciting undue irritation.

When the artery is diseased, or abnormally brittle, from the fibrous, cartilaginous, earthy, or fatty degeneration of its tunics, it may become necessary to employ a flat ligature, consisting of two or more silk threads, carefully waxed, and arranged side by side, or of a piece of soft, narrow braid, drawn so gently around the vessel as merely to approximate its serous surfaces. In using the round ligature, the division of the inner and middle tunics is aimed at, as this is most favorable to adhesion; but in this case the object is to preserve their integrity, so as to promote the retention of the cord until a permanent clot is formed. If this precaution be neglected, the cord may fall off permaturely, and thus occasion secondary hemorrhage. Instances occur in which the fragility of the arteries is so great as to render them incapable of bearing even this degree of pressure; and then the only resource is to include the vessel along with a portion of muscular or aponeurotic substance in a flat ligature. Such a procedure is much more rational than the practice, formerly recommended, of tying the vessel over a roll of adhesive plaster, an operation which could hardly fail to be followed by mischief.

In regard to the propriety of drawing the ligature so firmly as to divide the inner and middle tunics, no doubt is any longer entertained by enlightened practitioners. In the time of Scarpa much disputation prevailed respecting this point in the ligation of arteries, it having been alleged by this distinguished surgeon, on the strength of numerous experiments, that a cure could be effected quite as rapidly, and, in the end, more safely, simply by placing the serous surfaces gently in contact with each other. It was supposed that the part, treated in this way, would unite by direct adhesion, and that, consequently, when the ligature finally became detached, there would be much less risk of hemorrhage than when the vessel is lacerated and contused by the ruder method of procedure above described. Plausible as this theory may, at first sight, appear, it is found to be wholly unreliable in practice, for the very reason which induced Scarpa and his followers to

advocate its adoption, the ligature being not only a much longer time in separating, but the two ends of the artery being much less effectually occluded. When it is recollected that a certain degree of inflammation is necessary, after this operation, in order to afford the requisite amount of plasma, for gluing the inner clot to the surface of the vessel, it is reasonable to suppose that it would be much more easily induced by a partial division of the inner and middle tunics than by the mere approximation of the opposite sides of the tube ; and this is precisely what the general experience of the profession has at length established in relation to the subject.

When a considerable portion of neighboring tissue is obliged to be included along with the artery, the best instrument for performing the operation is a sharp tenaculum, with an eye near its point, as seen in fig. 281 ; a curved needle armed with a double ligature ; or Physick's artery forceps, fig. 282.

Fig. 281.

Fig. 282.

Tenaculum-needle, armed with a Ligature.

Physick's Artery Forceps.

An artery is sometimes rendered incapable of bearing a ligature in consequence of the softening of its tunics by inflammation. Such an event, which is often exceedingly perplexing, is most liable to happen in cases of secondary hemorrhage after wounds and amputations. The remedy is to isolate the vessel a short distance beyond its diseased limits, and to ligate it there in the usual manner ; or, this being impracticable, to tie the diseased part along with more or less of the surrounding tissues ; or, this also failing, to cut down upon and secure the main trunk of the artery.

In tying an artery in its continuity, whether as a means of arresting hemorrhage or of curing disease, the ligature is passed around the vessel by means of an aneurism-needle, fig. 283, a kind of blunt tenaculum, with an eye at the free extremity. The point of the instrument is gently carried around the vessel, without including any of the accompanying structures, steady counterpressure being made with the end of the forefinger, especially as it penetrates the connective tissue.

Fig. 283.

Aneurism-needle armed with a Ligature.

The precise situation of an artery is determined by its pulsation, and by its anatomical relations. Sometimes its course may be accurately defined by stretching a line from one point to another. At the commencement of the operation, the limb should be forcibly extended, as the muscles and tendons will then be rendered most prominent ; but, as the dissection proceeds, the object will be greatly promoted by flexing the limb in order to relax the soft parts. That the artery may not be wounded, its sheath should be carefully pinched up with the forceps, nicked slightly with the scalpel, as in fig. 284, from Erichsen, and then slit open to the distance of a few lines upon a grooved director. Isolation is best effected with the point of this instrument, either alone, or aided with the forceps and

Fig. 284.

Exposure and Opening of the Sheath.

finger nail. The proper sheath must be disturbed as little as possible, as it is intimately connected with the nutrient vessels, the injury of which might occasion softening, ulceration, or gangrene of the artery. The muscles are separated with the handle of the scalpel, without any material interference with the integrity of their fibres; and great care is taken, before commencing the incisions, to ascertain the situation of the superficial veins, by compressing the parts above the seat of the proposed operation, as it is very important that they should not be wounded.

The practice of applying two ligatures, and dividing the artery between them, is now very properly abandoned. The operation, which dates as far back as the time of Aetius, was revived by Mr. Abernethy, through whose influence it became for a while quite popular. It was soon found, however, that it was liable to be followed by secondary hemorrhage, owing chiefly to the injury inflicted during its execution, and it has, therefore, deservedly fallen into desuetude.

It was also in the operation of Aetius that some of the surgeons of the last century employed what was termed the reserve ligature, intended as a ready resource in sudden emergencies. The cord was placed loosely around the artery, to be tied instantly in the event of hemorrhage, from the premature detachment of the original ligature. Experience, however, soon showed that the procedure, instead of answering the design for which it had been intended, had a direct tendency to bring about the mischief, from its liability to produce ulceration of the denuded and tortured vessel. Its evils, indeed, are so palpable that there is no probability that it will ever be revived by any intelligent surgeon.

When an artery as, for instance, the femoral, is cut completely across in the continuity of a limb, two ligatures are necessary, one for the cardiac, and the other for the distal, extremity of the vessel. The reason of this is that, however securely the cardiac end may be tied, there will inevitably be more or less hemorrhage from the lower end, unless this be tied also, in consequence of the activity of the recurrent circulation. Every one who has ever had occasion to ligate the brachial artery at the bend of the arm, on account of injury inflicted upon the vessel in bleeding, must have seen that the hemorrhage was only partially controlled by tying its upper extremity. The blood, under such circumstances, wells up from the lower part of the artery as water bubbles up from the bottom of a spring; it does not issue in jets, or in a saltatory manner, as when it proceeds from the upper orifice, but lazily, and of a dark color, the bleeding resembling that of a vein rather than of an artery; and thus the hemorrhage goes on, with little or no intermission, until it is arrested by ligature, or until it proves fatal. The flow may, it is true, be temporarily stopped, during an attack of syncope; but even then seldom perfectly, for the reason, apparently, that the vessel here does not possess the same power of contraction and retraction that it does above, and is, therefore, not capable of forming any efficient clot, either external or internal.

The changes which occur in an artery after the application of a ligature are essentially similar to those which occur when the bleeding is arrested spontaneously. The first thing that happens, after such an operation, is the coagulation of the blood within the artery as high up, generally, as the first considerable collateral branch, thus forming what is named the internal clot. The external clot is, of course, wanting, a circumstance which constitutes the main difference in the two cases. The injured tunics, becoming inflamed, the cellular elements, particularly those of the intima or internal coat, multiply, and they, along with wandering lymph cells, give rise to a plastic formation, which grows between the clot and the ligature, and firmly and permanently fixes the former in its situation. In the course of a few days granulations spring from the plastic formation, extend into the clot, and cause it to disintegrate and finally to disappear. At about the sixth day the plastic formation begins to show signs of organization, and is soon permeated by a rich capillary network. Between the fifteenth and twentieth day, an anastomosis is established between the former vessels and those of the wall of the artery, the communication being established at the point at which the internal and middle coats have been divided by the ligature. Finally, after an indefinite period, the plastic formation being transformed into cicatricial tissue, disappears, and the corresponding portion of the artery is converted into a dense, fibrous cord.

The changes experienced by the arteries, the clot, and the plastic formation in their interior, after the application of the ligature, are admirably illustrated in the adjoining sketches from Dr. E. O. Shakespeare, to whose researches we are mainly indebted for a knowledge of the part played by the endothelial elements of the internal coat of the vessels in the process of repair. Fig. 285 represents a transverse section of the femoral artery of a dog forty-eight hours after deligation. At a and c the external and adventitious coats show proliferation of their cellular elements; at m the same change has occurred in

the middle tunic; at *e* the folds of the elastic layer of the inner coat are still very distinct; and at *p* the plastic material, formed principally by proliferating endothelial cells, is very conspicuous. Fig. 286 exhibits the artery eight days after the operation. At *p* granulations are seen springing from the plastic formation. They consist of spindle cells, the direction of the long axis of which is in the main parallel to the axis of the granulations.

Fig. 287, from O. Weber, represents the artery fifty days after deligation: numerous vessels are seen coming from the external coat, *Z*, to communicate with the newly-formed vessels of the plastic clot, *Th.*

Effects of Ligation, at the end of Forty-eight Hours.

It is impossible to state, except in a general manner, how long an internal clot must be in order to effect thorough closure of an artery, so as to prevent hemorrhage on the separation of the ligature. There is unquestionably less danger of hemorrhage when the distance between the ligature and the first large collateral branch is considerable than when the reverse is the case; and yet instances not unfrequently arise in which no bleeding takes place, although there is hardly any internal clot at all. Such an occurrence can only be explained upon the assumption that the plasma poured out during the progress of the inflammation provoked by the pressure of the ligature serves under such circumstances the purpose of a clot, which, hermetically sealing the mouth of the vessel, opposes an effectual barrier to the effusion of blood on the detachment of the ligature. Secondary hemorrhage will be most likely to occur when there is extensive separation of the sheath of an artery, in our attempts at isolation, thereby cutting off the supply of blood and nerve fluid from its tunics, and, as a necessary consequence, causing gangrene and premature detachment of the slough. In such an occurrence, which is sometimes unavoidable, the best plan is to adopt the practice of Professor Toland, of San Francisco, of employing two ligatures applied in such a manner as to exclude the denuded portion of the vessel entirely. The operation is based upon the fact that the integrity of the sheath of an artery is just as necessary to the preservation of its vitality as the periosteum is to that of a bone.

The period at which a ligature is detached varies with many circumstances, of which the principal are, the size of the cord and the manner in which it is tied, the state of the
Fig. 286.
Effects of Ligation, at the end of Eight Days.

Fig. 287.

Effects of Ligation, at the end of Fifty Days.

artery, and the amount of the resulting inflammation. A small ligature will, other things being equal, be separated sooner than a large one, and a firm sooner than a loose one; a sound artery will be longer in throwing it off than a diseased one, simply because it has more power of resistance. A ligature upon the brachial artery will generally be detached in about ten days; upon the femoral, in from twelve to fourteen; upon the external iliac, in sixteen; upon the common iliac, in about twenty-one. To this rule there are, of course, many exceptions. I recollect an instance in which, after an amputation of the leg, the ligature was still

firmly adherent to the anterior tibial artery at the end of the fourth month. Dr. Lopez, of Mobile, communicated to me the particulars of a case in which the separation was not effected before the end of the eleventh month; and Professor Eve met with one in which it did not take place until after the thirteenth month. Such occurrences usually depend either upon the faulty manner in which the operation is performed, or upon the presence of an extraordinary quantity of organized plasma, interfering mechanically with the detachment of the thread.

When a ligature is indisposed to come away, its separation may generally be promoted by making, once every twenty-four hours, gentle traction upon it; great care and judgment, however, must be exercised in performing the operation, otherwise the patient may not only be subjected to severe pain, but to the risk of secondary hemorrhage.

The detachment of the ligature is effected by ulcerative absorption, and, if the mass be carefully inspected, it will be found to embrace a dead portion of the artery in the form of a slough.

When the cord is drawn very tightly, the corresponding part of the artery is strangulated, if not at once, at any rate, within a few hours; but, in general, the process takes place more tardily, and thus affords the two ends of the vessel time to prepare and fortify themselves for the approaching crisis. If we study the whole subject minutely, it will be found to embrace the following facts :—first, the strangulation and death of the vessel at the site of the ligature; secondly, the adhesion of the clot to the inner surface of the vessel, speedily followed by its replacement by organized tissue; thirdly, ulceration and the consequent separation of a part of the artery, thus producing a gap in its continuity; and, lastly, the disappearance of the new tissue and the transformation of each extremity of the tube into a dense, fibrous cord. In addition to these changes, there is occasionally slight suppuration, the matter usually presenting itself in the form of a little abscess. When an artery is tied at its extremity, as in an amputation or the extirpation of a tumor, the part of the vessel beyond the seat of the ligature mortifies, and is eventually detached as a slough.

Percutaneous—more properly called subcutaneous—ligation of the arteries in their continuity for the arrest of hemorrhage may occasionally be advantageously practised. It is particularly applicable to hemorrhage of the palm of the hand and sole of the foot, attended with inordinate swelling of the parts, rendering it difficult, if not impossible, to expose the bleeding vessel, and to tie it in a satisfactory manner. The operation consists, as the term implies, in carrying a stout needle, more or less curved, and armed with a strong thread, through the skin around the artery at a distance of one-third of an inch to an inch and a half from its track, so as to include a considerable portion of soft structure, and then bringing the needle out through the skin near the opening of entrance, and tying the ends of the thread over a roll of adhesive plaster. The vessel is thus firmly embraced in the loop of the ligature, which may generally be withdrawn by the end of the third day, or even before, as by that time complete occlusion will have taken place.

Subcutaneous ligation, mentioned by Ledran, in 1720, was originally practised by Professor Middledorpf, of Breslau, who has adduced a number of cases illustrative of its value. In this country the subject was first brought prominently before the profession by Dr. H. Z. Gill. The operation, which is performed with a slightly curved and somewhat flexible needle, armed with a thread or silver wire, is obviously not adapted to the larger arteries, as the ligature would necessarily include the corresponding vein, the obliteration of which might be followed by most disastrous consequences, independently of the compression of the large nerves, which are often in such close relation with the bloodvessels.

The discovery of the use of the ligature is due to Ambrose Paré, in the sixteenth century, prior to whose time surgeons were in the habit of stanching hemorrhage with the actual cautery, hot pitch, and all kinds of styptics, of the most cruel and barbarous nature. " For the good of mankind," says this great man, " and the improvement and honor of surgery, I was inspired by God with this good thought." Paré himself fully appreciated the utility of his invention, but his contemporaries spared no pains to undervalue it, and to revile and persecute its author, subjecting him to the humiliation of searching the writings of the ancient fathers of medicine for traces of the use of the ligature as a justification of his practice. Gourmelen, the jealous and malignant President of the College of Physicians of Paris, made himself particularly conspicuous on the occasion, and thus earned an infamous reputation; for the only act by which he is now remembered is his bitter and unrelenting persecution of Paré, rendered immortal by his great achievements.

2. *Acupressure.*—Acupressure, as a means of arresting hemorrhage, was devised by Sir James Y. Simpson, who published his first account of it in 1860; and, although it has attracted great attention since, more especially in Europe, and its results have, in the main, been of a very flattering character, time alone can determine its ultimate fate. That it is destined entirely to supersede the use of the ligature, so easy of application, so efficient in its action, and so universally approved, even its warmest advocates will hardly claim. In this country acupressure has made little progress; and, with the exception of Hewson, L. Weber, and Hutchison, all of whom have written able papers upon the subject, few, if any, prominent surgeons employ it. I have myself seldom used it, having always been satisfied with the harmless character of the ligature and its efficiency as a safe and ready hemostatic agent.

The advantages claimed for this operation over that of the ligature are, first, that it is more easy, simple, and expeditious of execution; secondly, that the acupressure needle does not, like the ligature, provoke irritation, much less suppuration, ulceration, or mortification at the seat of the constriction; thirdly, that the instrument may generally be removed, even in an artery of large size, as, for example, the femoral, at the end of the second or third day; fourthly, that the wound, other things being equal, is more liable to unite by the first intention; fifthly, that there is much less risk of erysipelas, pyemia, phlebitis, abscesses, traumatic fever, and secondary hemorrhage; and, lastly, that it may be safely employed in diseased arteries, too soft, brittle, or friable to bear the pressure of a ligature. It may also be used with great advantage when the blood oozes from numerous points, as in certain operations upon the vulva and other regions where ligation is impracticable. In regard to the occurrence of secondary hemorrhage the results of acupressure are highly flattering. Pirrie and Keith had, up to 1869, treated nearly one thousand vessels by this method, with less than five cases of bleeding after the withdrawal of the needle.

Acupressure may be practised according to different methods, of which, however, only four need to be here described, as they have virtually superseded all the rest. Of these some originated with Simpson himself; the others mainly with Knowles, Keith, and Pirrie, of Aberdeen, the latter of whom has greatly simplified the operation, and devised convenient names for the designation of its principal methods.

A formal description of acupressure pins and needles is unnecessary, as they may readily be obtained at any of our cutlers. They must, of course, vary in size and shape, according to the object in view, and be sufficiently strong to prevent bending, perfectly smooth, sharp-pointed, and coated with silver, nickel, or gold, although this is not absolutely essential. When such instruments are not at hand, convenient substitutes will be found in long shawl pins. Flexible steel wire is required only in one of the present methods of acupressure.

No special isolation of the artery is required, as when the ligature is used, and any bleeding veins may, if necessary, be very properly included along with that vessel without detriment. Occlusion is effected by fibrinous plugs, as in ordinary ligation, but, owing to the preservation of the vitality of the coats of the vessels, they are much more rapidly organized, and, consequently, less liable to lose their hold after the removal of the pin.

In the original operation of Simpson, the pin, previously oiled, is passed from without inwards through the skin, and thence on through the muscles and other structures down to, and underneath, the artery, in such manner as to obliterate completely its caliber by bringing together its opposite surfaces. The instrument is then pushed through the tissues on the other side from within outwards, so that, when the transmission is effected, the extremities shall rest upon the skin, while the middle firmly embraces the

Fig. 288.

Acupressure.

Fig. 289.
Acupressure, showing the manner in which the Ends
of the Pin project across the Skin.

artery. If the constriction is not sufficient to arrest the flow of blood, a ligature may be thrown tightly around the pin, as in the operation for harelip; but this will seldom be necessary, especially if the precaution be taken of inserting the compressor close to

the vessel, at a rather acute angle. The point of compression for the larger arteries should be at least six lines from the open orifice, and about half that distance for those of smaller size. The pin should be left entirely free during the application of the dressings, and in withdrawing it the parts must be well supported in order to avoid the risk of hemorrhage.

The annexed sketches show, at a glance, this method of acupressure. Fig. 288 displays the manner in which the instrument embraces and constricts the artery, while fig. 289 exhibits the extremities of the pin as they project through the skin. A good idea of it may also be formed by the manner in which the stalk of a flower is fastened to the lapel of a coat by transfixing the cloth with a pin.

In circumclusion, as it is called by Pirrie, the pin or needle, armed with a twisted wire, is passed completely under the vessel, which is then pressed firmly against it by means of a loop of wire hooked over its point, while the ends are fixed by a single twist around the pin, as in fig. 290.

In a torsoclusion, formerly described as the Aberdeen method, the pin is inserted into the tissues close to and parallel with the bleeding artery, and its point caused to emerge at a distance of several lines, as in fig. 291. The second step consists in giving a quarter rotation to the pin, so as to place its point above and at a right angle to the vessel; in pressing it well down, and in pushing this for some distance into the tissues beyond, so as to fix it there and maintain the twist, when the parts will present the appearance shown in fig. 292.

Fig. 290.

Circumclusion.

Retroclusion, so named because the pin is passed immediately behind the artery, consists of two steps. In the first the pin is entered a little to one side of the artery, caused

Fig. 291.
First step of Torsoclusion.

Fig. 292.
Second step of Torsoclusion.

to emerge, and passed in front and a little beyond the track of the artery, as in fig. 293. In the second step the head of the pin describes the fourth of a semicircle; its point is then sent behind the vessel, and pushed on until it is fixed in the tissues beyond, as in fig. 294.

Of all these methods of acupressure, torsoclusion deserves the preference, especially for large arteries; while retroclusion is very convenient for securing vessels of small size.

The period during which the pins should be retained must necessarily vary in different cases and under different circumstances. For a large artery, such as the femoral, a good

Fig. 293.
First step of Retroclusion.

Fig. 294.
Second step of Retroclusion.

average period is from forty-eight to sixty hours; for a small one, as the ulnar or radial, from twenty-four to thirty-six. A longer time should be allowed when the patient is

restless or affected with cough, vomiting, or high constitutional excitement, or when the local action is unusually great and rapid, threatening to run into suppuration, ulceration, or gangrene. Withdrawal of the pins is effected by a gentle twist of the thumb and fore-finger, everything like rudeness being avoided, lest it should provoke hemorrhage and interfere with the adhesions of the parts.

Substitutes for the Ligature and Acupressure.—As temporary substitutes for the liga-ture and acupressure numerous instruments have been contrived, all of which possess nearly the same mode of action. Professor N. R. Smith, of Baltimore, proposed noosing the extremity of the artery with a loop of fine annealed iron wire passed through a small, double silver tube and fastened to its free extremity, which has a slit on each side for the sake of greater security. The tube is brought out at the wound, and may be safely de-tached even from a vessel as large as the femoral artery on the second day after the ope-ration. The wire, in the act of removal, is carefully unrolled, and forcibly drawn with pliers through the canula in such a manner as to sever the artery as with a small écraseur.

The late Mr. Nunneley, of Leeds, employed a pair of forceps, delineated at p. 255, fig. 72, for arresting hemorrhage. He retained the instrument, hanging out of the wound, from thirty-six to forty-eight hours, and found the method so efficacious that he rarely employed any other. Mr. B. W. Richardson, of Dublin, uses a tubular compressor, and I myself long ago recommended for stopping bleeding in deep-seated arteries a pair of light forceps with a movable handle.

The *wire loop*, as a temporary expedient for arresting hemorrhage, is a modern device, first practised, a few years ago, almost simultaneously by Dr. A. M. Pollock, of Pittsburg, and Mr. Dix, of England. It consists in encircling the artery with a thread of silver or annealed iron wire, the ends of which, brought out at the surface one-fourth of an inch apart, are twisted together or tied upon the skin, over a short cylinder of wood, gutta percha, or adhesive plaster. The procedure is applicable to vessels in their continu-ity as well as to cut vessels, and, although the artery should always be separated from its accompanying veins, no harm is likely to result if they are embraced in the same loop. The period during which the loop should be retained varies, on an average, from two to five days. If taken off too soon, secondary hemorrhage might occur ; and, on the other hand, if kept on too long, dangerous ulceration. The easiest and safest way of effecting the removal of the loop is to roll one end, after it is cut, around a pair of forceps in the direction of its concavity. When an artery is thus secured in its continuity, the ces-sation of pulsation immediately above the loop will generally serve to show that the time has arrived when it may with propriety be taken off, or, at all events, when the pressure may be safely slackened, to be again tightened if there be a recurrence of pulsation.

In an article on the wire loop, in the New York Medical Journal for July, 1869, Dr. Pollock gave an account of twenty-six amputations in which he employed this method of treatment, the number of arteries thus secured being forty-seven, including seventeen femoral. In no instance did any accident arise that was justly attributable to the pro-cedure. In one case only was there secondary hemorrhage. The average period at which the wire was removed was about five days and a half.

While the wire loop does not, apparently, possess any advantages over acupressure, ex-cept that in certain situations it is more easily applied, it is unquestionably preferable to the ordinary ligature, inasmuch as it causes less irritation, is retained only for a comparatively short time, and is more frequently followed, in open wounds, by union by the first inten-tion. The most serious objection to it is the difficulty which sometimes attends its removal.

Dr. S. F. Speir, of Brooklyn, has described in the New York Medical Record for April, 1871, a very ingenious and useful contrivance, by which arteries may be perfectly

Fig. 295.
Artery Constrictor.

occluded, without any foreign material being left in the wound to interfere with its union. The instrument, delineated in fig. 295, and termed the *artery constrictor*, consists of a flat metal tube, from three to six inches in length, with a sliding steel rod, one end of

which terminates in a hook-shaped tongue, with which the vessel is constricted, while the other end has a screw arrangement, through which the tongue can be made to protrude from or retract within the sheath.   The divided artery having been brought out of the wound by a tenaculum or pair of forceps, the tongue of the constrictor is placed around, and drawn tightly upon it.   As soon as the screw meets with a considerable degree of resistance, the instrument is detached.   When the operation is properly performed, it will be found that the artery is completely occluded by the manner in which the internal and middle tunics are ruptured and invaginated, at the same time that the outer one is drawn more or less firmly over them.   The advantages of this mode of treatment are said to be its efficiency, safety, and facility of application ; and I am informed by Dr. Speir that it has been successfully employed in amputation at the hip, of the thigh, and of the leg, and applied to the carotid and femoral arteries for the cure of aneurism.

3. *Compression.*—Although ligation and acupressure are the most certain means of arresting hemorrhage, cases occur to which they are either not at all adapted, or where, from the great depth and narrowness of the wound, they are impracticable.   It is then that compression becomes available ; an agent often hardly less valuable than either of the other methods.   It is particularly serviceable when the injured vessel lies upon a bone, as in injury of the brachial and temporal arteries ; in wounds penetrating deep cavities, as the thoracic and abdominal ; and, lastly, when the blood issues from a considerable number of small vessels instead of escaping from one large one.

The compression may be temporary or permanent, according to the exigencies of the case.   Temporary compression is made with the hand, finger, tourniquet, or compress and bandage, until the injured artery can be ligated, or secured in some other effectual way.

Fig. 296.

Tourniquet applied to the Femoral Artery.

In permanent compression, the application is continued until the vessel is completely obliterated, whether the time be short or long.

Temporary compression is necessary chiefly in cases of sudden emergency, as, for example, when an individual is stabbed in the femoral artery, and the surgeon cannot obtain any assistance in tying the vessel. In such an event, an attempt is made to arrest the hemorrhage with a tourniquet, fig. 296, or with a graduated compress and bandage ; the former being placed directly over the course of the artery from which the bleeding proceeds, or, if this be impracticable, over the main trunk of the limb, and the latter directly over the wound as well as for some distance above, along the track of the vessel.   In either case, it is to be borne in mind that the compression, even if maintained only for a few hours, may become a source not only of excessive pain, but also of mortification.   The greatest possible vigilance should, therefore, be exercised in its employment.

The original idea of the tourniquet is generally ascribed to Morel, a French military surgeon, who employed it in the treatment of various kinds of wounds at the siege of Besançon, in 1674.   Hans von Gerstorff, however, had previously devised an instrument for arresting hemorrhage, and out of these crude attempts arose the beautiful and very perfect contrivance now known as the tourniquet of Petit, delineated in fig. 296.

When the ordinary tourniquet is not at hand, very efficient compression may be made by tying a piece of bandage, a cravat, or a handkerchief loosely around the limb, and then twisting it firmly over a thick compress by means of a stick, fig. 297, a cane, or the hilt of a sword, fig. 298, inserted underneath it.   This contrivance, usually called the field tourniquet, because it was originally employed on the field of battle, may advantageously be applied when a surgeon is obliged to amputate an extremity without having a sufficient number of intelligent assistants, although it labors under the inconvenience of not always concentrating the pressure upon the spot where it is most needed.   For this reason the common tourniquet is decidedly preferable.

For arresting hemorrhage in gunshot and other wounds on the field of battle, the most effective tourniquet is that of Mr. Lambert, of Peekskill, consisting of two concavo-

convex pads of tin plate, connected by a non-elastic ribbon, nearly two feet in length by an inch and a half in width. When the instrument is applied, one of the pads rests upon the main artery of the limb, and the other upon a point directly opposite, without the slightest intermediate constriction, and, consequently, without any embarrassment whatever of the venous circulation.

Fig. 297.

Field Tourniquet; Handkerchief and Stick.

Fig. 298.

Field Tourniquet; Handkerchief and Sword.

Compression with the hand, thumb, or finger may often be advantageously employed for the arrest of accidental hemorrhage, until a ligature can be applied; and it is also occasionally resorted to for the purpose of controlling the circulation in the main artery

Fig. 299.

Digital Compression of the Brachial Artery.

Fig. 300.

Digital Compression of the Femoral Artery.

of a limb during amputation. In the upper extremity it is generally applied to the brachial artery, as it courses along the inner border of the flexor muscle; and in the

lower, to the femoral artery where this vessel lies upon the pubic bone beneath Poupart's ligament. The annexed drawings, figs. 299 and 300, are illustrative of the subject.

The arteries which most readily admit of indirect temporary compression are, first, the common carotid, with some of the branches of the external carotid, as the facial, coronary, temporal, and occipital; secondly, the subclavian, axillary, brachial, radial, and ulnar; and, lastly, the iliac, femoral, and popliteal. The circulation of the abdominal aorta may be arrested in a similar manner, especially in lean subjects, as has been shown in a multitude of cases of hemorrhage of the uterus, wounds of the groin and thigh, and in amputation at the hip-joint, in the latter of which, as experience has proved, this mode of compression is of the greatest consequence as a means of preventing loss of blood.

1st. The most eligible point for compressing the common carotid is the omo-hyoid angle, between the sterno-cleido-mastoid muscle and thyroid cartilage. The vessel here is situated more superficially than lower down, and may, especially if it be pushed a little over towards the middle line, be readily forced against the bodies of the cervical vertebræ. If the finger or instrument, whatever this may be, be applied perpendicularly, or carried too far outward, there will be danger of arresting the circulation in the jugular vein, and thus causing serious cerebral disturbance, to say nothing of the injurious effects that might result from the compression of the phrenic, sympathetic, and pneumogastric nerves. In any event the operation is always painful, and can seldom be borne for any length of time. When it is obliged to be protracted, the best plan is to use alternate pressure with two fingers, applied to different portions of the vessel.

The pulsation of the facial artery may be effectually controlled by pressure made with the finger against the outer surface of the lower jaw, a little in front of the masseter muscle. The vessel is so superficial that it may always be readily found.

The coronary artery is compressed by seizing the lip with the the thumb and forefinger, or with a Nunneley's forceps, on each side of the wound, fissure, or disease, otherwise the hemorrhage will only be partially controlled, as is evinced in the operation for harelip and in the excision of carcinomatous growths.

The temporal artery is compressed in front of the ear, about two lines from the tragus, and a little above the zygomatic process. The vessel, at this point, is very superficial, and is, therefore, easily flattened against the bone, from which it is separated only by a thin layer of fibro-muscular substance. The supraorbital artery is controlled by the application of the finger immediately above the supraorbital notch, at the distance of about an inch from the root of the nose; and the occipital, in the space midway, or nearly midway, between the mastoid process and the attachment of the complexus muscle.

2dly. Compression of the subclavian artery is often required on account of wounds and operations in and upon the axilla, the lower part of the neck, and the upper part of the chest. The necessary pressure, which, however, can seldom be borne long, owing to the presence of the axillary plexus of nerves, may be made with the instrument delineated at p. 517, the thumb, or the handle of a stout, well-covered key, applied to the supraclavicular fossa, near the outer border of the sterno-mastoid muscle, the shoulder being forcibly depressed. The artery at this point lies upon the first rib, and can be easily controlled, provided the pressure be directed downwards and somewhat inwards, in the line of the bone.

The axillary artery is most effectually compressed against the head of the humerus, while the arm is extended at nearly a right angle with the trunk. The vessel, when the limb is in this position, is put considerably upon the stretch, and is thus easily maintained in contact with the bone.

Compression of the brachial artery may be effected in almost any portion of the extent of this vessel, as it courses along the biceps and coraco-brachial muscles, but cannot be maintained for any length of time on account of the pain experienced in the accompanying nerves. It is most conveniently made by grasping the limb with the thumb and fingers, the latter being applied in such a manner as to press the artery perpendicularly against the humerus. The circulation is always easily controlled by the tourniquet. Hemorrhage of the brachial artery from venesection has been temporarily arrested by flexing the forearm forcibly upon the arm. A similar procedure will stop the pulse at the wrist.

The proper place for arresting the circulation in the radial and ulnar arteries is the inferior third of the forearm, where these vessels are not only quite superficial, but where they may easily be flattened against the bones. Temporary compression may conveniently be made with the fingers; permanent, with two small compresses, confined in such a manner as not to embarrass the return of the venous blood. The arteries of the fingers

may be controlled by pressure applied at the junction of the anterior with the external surface.

3dly. The aorta in lean subjects, or even in a person of ordinary embonpoint, with empty bowels, may easily be compressed at the umbilicus against the lumbar vertebræ, either with the fingers, or, what is better, a Pancoast's tourniquet. The force should be applied a little to the left of the middle line, so as to avoid the vena cava, and the abdominal muscles should be well relaxed by the elevation of the hips and shoulders. This mode of compression is often highly serviceable in arresting uterine hemorrhage, and is now almost universally employed as a means of controlling the circulation in amputation at the hip-joint. Bleeding from a wound of the external iliac artery may also thus be commanded. In using the tourniquet, care must be taken not to bruise any of the abdominal viscera. In ordinary cases, in thin subjects with empty bowels, compression of the aorta is usually easily effected with the thumbs, or thumbs and fingers.

The circulation of the common iliac artery may be controlled by relaxing the parieties of the abdomen and making pressure against the brim of the superior strait of the pelvis. To command the external iliac, the force must be applied against the inner border of the psoas muscle. In neither of these situations, however, can compression be employed with much certainty of success; but the circulation can be effectually stopped by compressing the common iliac artery through the rectum with the hand, as suggested by Dr. Frank Woodbury, of this city, or with a lever of wood, as practised by Mr. Davy, of London.

In the lower extremity, compression of the femoral artery, at its exit from the pelvis, is almost exclusively relied upon for commanding the circulation in amputations, resections, and accidental hemorrhage. Louis was the first to substitute this method for the tourniquet in ablation of the thigh, and the practice is now very common among the best surgeons in this and other countries. One decided advantage which it possesses over the tourniquet is that it is less painful, more certain, and attended with much less venous hemorrhage. The compression is generally made with the two thumbs placed the one upon the other, just beneath Poupart's ligament, and midway between the pubic symphysis and the anterior superior spinous process of the ilium. In order that the pressure may be perpendicular, and, therefore, the more effective, it should be made, as Malgaigne has very properly remarked, rather obliquely upon the artery, upwards and backwards, forming with the horizon an angle of 45°. When the assistant is unwilling to trust himself with his thumbs or fingers, a large key, with an appropriate pad attached to the handle, may be used as a substitute.

The femoral artery in the middle third of the limb may be effectually compressed against the thigh-bone, either with the fingers grasping the limb, tourniquet, or the compressor described at p. 517.

The tourniquet is sometimes applied to the popliteal artery, opposite the knee, a tolerably thick roller, pad, or compress being placed beneath the instrument in order to render the pressure more effective. Compression with the fingers is difficult and inoperative, on account of the great depth of the vessel.

The tibial arteries can be compressed only in the lower portion of their extent, as they are there comparatively superficial, while higher up they are deeply buried among the muscles. The anterior vessel is commanded as it passes along the side and front of the bone, between the tendon of the common extensor of the foot and the proper extensor of the great toe. A tourniquet applied here, over a hollow splint, stretched along the inner and back part of the limb, as suggested by the late Dr. Alexander H. Stevens, in 1818, will readily control the circulation. The posterior tibial artery is compressed between the heel and the ankle, its pulsation serving as a guide to its situation. The dorsal artery of the foot is easily controlled, as it runs down across the instep, being covered merely by aponeurosis, connective tissue, and skin.

The *veins*, from their superficial situation and the greater softness of their tunics, are much more easily compressed than the arteries. The deep-seated ones, however, often require a good deal of force, and even then their circulation is sometimes controlled with difficulty.

The proper place for compressing the external jugular vein is about one inch above the clavicle, at the centre of this bone, in the inferior triangle of the neck, where it empties into the subclavian. The vessel runs perpendicularly across the sterno-mastoid muscle, in the direction of a line drawn from the angle of the jaw to the middle of the clavicle.

The subclavian, axillary, and brachial veins accompany the arteries of those names, and cannot be compressed independently of them, except in the case of their division.

The cephalic and basilic veins with their branches are easily commanded at the bend of the arm.

The saphenous and femoral veins are most effectually compressed in the upper portion of Scarpa's triangle, from an inch and a half to two inches below Poupart's ligament. The former vessel is superficial, and the latter lies in close contact with the inner border of the femoral artery.

In *permanent compression* the force is applied in one of two ways, either directly or indirectly. The former method is particularly adapted to the suppression of hemorrhage from deep wounds, as in the lateral operation of lithotomy; in wounds of the rectum, whether accidental or wilful; in bleeding of the nose and uterus; in the removal of tumors from the maxillary sinus; in the extraction of teeth; in the extirpation of the eye; and, finally, in wounds of the middle artery of the dura mater, as well as in a number of injuries in other regions of the body.

The great objection to this mode of compression is its liability to be deranged and to produce severe pain and inflammation, the latter of which is often sufficient to cause profuse suppuration. It should, therefore, never be employed with a view of arresting hemorrhage from a large artery, or even from a small deep-seated one, if it be practicable to apply a ligature, as this is, of course, always the most certain and efficient means; but this objection does not obtain when the blood proceeds from a bleeding cavity, or when it oozes from the bottom of a recent wound. In such a case, indeed, compression must be used at all hazard, for there is frequently no other way by which the flow can be arrested.

The compression may be made with a graduated pad and roller, or by means of sponge, cotton, wool, patent lint, or any other porous substance. Whatever article be employed, the bleeding surface must previously be freed from coagula, in order that the compress

Fig. 301.

Plan of a graduated Compress. *a.* The Artery wounded. *b, b.* The graduated Compress, arranged so that the apex of the cone is in immediate contact with the bleeding Orifice, while its Mass occupies the general Wound, and projects somewhat above the Integumental level.

may be placed directly in contact with the orifices of the vessel, as exhibited in fig. 301. When the blood proceeds from a large artery, the circulation must be controlled, during this part of the procedure, with the finger or tourniquet applied some distance above the wound. The compress is then thrust gently but firmly into the breach, the smallest piece being placed directly upon the mouth of the vessel, the next above this, and so on until a sufficient number have been applied, when the operation is completed by bandaging the limb from its distal extremity upwards, care being taken that the pressure be made in as equable and uniform a manner as possible. The part is then put at rest, in an elevated position, and action moderated by the use of cold water, anodynes, and other suitable means. The dressings are frequently examined, but not disturbed under four or five days, unless they become displaced, or offensive from the discharges.

When hemorrhage proceeds from a wound, as, for example, from that made in lithotomy, the part must be plugged with a sponge, or a piece of patent lint, the hollow of which is filled up with similar material, or raw cotton, an instrument having previously been introduced through the foreign substance to conduct off the urine. A like plan is pursued in bleeding of the rectum. In hemorrhage of the uterus, the vagina is plugged; in epistaxis, the nostrils.

In injuries of the bones, a plug of soft wood, as a piece of pine, is sometimes used. In compound fracture of the skull, attended with lesion of the middle meningeal artery, running in an osseous canal, such an expedient is often the only one which can be successfully opposed to the hemorrhage. Bleeding of the nutrient artery of the long bones is occasionally stopped in a similar manner.

In some cases the tissues of the part whence the hemorrhage proceeds are employed as the compressing agents. In the operation for harelip, for example, the simple approximation of the edges of the fissure by the twisted suture effectually arrests the flow of blood from the coronary arteries.

The compression is said to be indirect or lateral, when it is applied to the track of the injured vessel instead of to its orifice. It is generally a more eligible way of arresting hemorrhage, as it is free from the objections that have been urged against direct compression, with which, however, it is occasionally combined. The best mode of effecting it is to place a long and rather narrow compress over the course of the artery, extending from the neighborhood of the wound some distance above, and to confine it by means of a roller,

commencing at the distal portion of the limb, and carried upwards in such a manner as to afford equable support at every point. In other respects, the treatment is conducted as in direct compression. This mode of management is often employed, with the happiest effects, in wounds of the brachial artery, at the bend of the arm, caused by venesection.

Digital compression has been successfully employed in hemorrhage of wounded arteries, and is worthy of further trial. It is conducted by a relay of assistants in the same manner as in the treatment of aneurism, described in the next chapter. The procedure is particularly applicable to hemorrhage of the brachial artery.

4. *Torsion.*—Torsion of the arteries is an old procedure, mentioned by Celsus, and reintroduced to the notice of the profession by Thierry, Amussat, Velpeau, and others; at one time pointedly condemned, at another immeasurably lauded, and even now opinion is by no means settled in regard to its safety as a general hemostatic agent, although the experience of Syme, Humphry, Bryant, Hewson, Tillaux, and others goes to show that it may be confidently applied to all arteries of the extremities, healthy and diseased, and also to such arteries of the trunk as do not exceed the volume of the femoral. The operation, which answers admirably in the inferior animals, as a substitute for the ligature, is executed with two pairs of forceps, as seen in fig. 302; a

Fig. 302.
Torsion-forceps.

small one for drawing out the artery by grasping it horizontally, and a long, stout one provided with a slide and serrated blades, for twisting it in its longitudinal axis; from six to eight turns being required, according to the size of the vessel, to lacerate and bruise its tunics so as to intercept and coagulate its contents. The vessel, properly isolated, must be held firmly, and twisted sharply until all resistance is overcome. When the artery is inflamed, softened, ulcerated, or rendered fragile from fatty degeneration, the operation must be performed more cautiously, with less force, and fewer rotations. The end of the vessel must not be twisted off; and the current of blood should always be allowed to enter the tube before the forceps are removed, in order to test the completeness of the occlusion, as the safety of the procedure must necessarily depend upon the manner in which this has been effected.

When torsion is properly executed, the inner and middle coats of the artery are not only lacerated, but the resulting shreds are more or less incurvated, or bent across the caliber of the vessel in such a manner as to form almost complete valves, which, while they oppose the flow of blood, entangle the fibrin of that fluid, and thus accelerate its coagulation. The outer tunic, on the contrary, is simply twisted, not broken up, an arrangement which adds greatly to the safety of the patient.

The advantages of torsion are that it favors the repair of wounds, and lessens the danger of suppuration; its disadvantages, that it is sometimes troublesome, and that it does not always arrest bleeding. The risk of secondary hemorrhage is inconsiderable, if the operation be done with due caution.

The annexed cut, fig. 303, represents the torsion-forceps of Dr. Addinell Hewson, consisting of two sets of blades, one broad and flat, for seizing and drawing out the artery; the other, a much smaller instrument, duck-bill shaped or curved at the point, and designed for dividing the coats of the vessel. The torsion is effected by rotating the forceps upon their axis, from two to three turns being sufficient to insure the occlusion of the largest vessel by lacerating the two inner coats and bruising the outer one, these effects being highly favorable to the coagulation of the blood and to the stoppage of hemorrhage. In an artery of the size of the femoral it is proper to let the forceps hang for a few minutes after the torsion is completed; or, instead of this, another turn may be made, in order to fix the twist more securely.

Torsion, as effected with the common forceps, is represented in fig. 304, from Follin, the twist being so firm as to prevent the possibility of undoing itself.

5. *Forced Flexion.*—This mode of treatment, introduced mainly through the influence of Dr. Heath, of Newcastle-on-Tyne, although previously practised by others, as Malgaigne and Richet, is applicable exclusively to the arteries of the extremities, and commends itself by its great simplicity, the principle of treatment consisting in moderating and restraining the flow of blood by overflexion of the joints. In wounds of the arteries

Fig. 303.
of the forearm and palmar arches, the former should be bent on the arm, the hand being pronated, and either flexed or extended at the wrist. For the arrest of hemorrhage of the lower extremity, a roll of lint, or other soft material, having been placed in the ham, the leg should be flexed on the thigh and the thigh on the abdomen, and confined by means of adhesive strips or a roller.

6. *Styptics.*—Styptics are remedies which arrest hemorrhage by their direct influence upon the blood, and the arteries furnishing it. They comprise a long and varied catalogue of articles, some of which produce merely an astringent effect; others act apparently mechanically; and others, again, are escharotic, destroying both the vessels and the connecting tissues.

The most powerful, and, at the same time, the least objectionable styptic at present known is Monsel's salt or subsulphate of iron. It is applied either in substance, or, what is preferable, in strong solution upon cotton or patent lint, and possesses the property of instantaneously coagulating the blood, converting it into a very dense, insoluble clot, which continues to increase and to harden for several hours afterwards. What adds greatly to the value of this remedy is its entire freedom from causticity and its remarkable antiseptic property. It is particularly adapted to hemorrhage of the nose, mouth, throat, and uterus, as well as of

Fig. 304.

other parts of the body where it is impossible to ligate the bleeding vessels, on account of the great depth at which they are situated. One part of the officinal solution diluted with from four to six times that quantity of water is an efficient hemostatic for ordinary purposes. The wound, well wiped as a preliminary measure, is covered with a thick compress wet with the fluid, and confined by a suitable bandage. Lint, thoroughly saturated with a solution of the salt, and then dried and rolled up makes an excellent extemporaneous styptic.

Among the minor and less reliable styptics are alum, sulphate of copper, creasote, and matico. Of these, the first is by far the most valuable. It may be applied in saturated solution, or in powder, upon patent lint, directly to the bleeding surface, previously freed of clots, and generally produces a powerful astringent effect, causing speedy coagulation of the blood, and marked

Hewson's Torsion-forceps.   Mode of applying Torsion.

contraction of the vessels, without necessarily provoking suppuration. Sulphate of copper may be used in a similar manner, or in the form of a stick, held firmly for some minutes upon the oozing capillaries. Creasote and matico possess none of the hemostatic qualities formerly ascribed to them, and are now never applied with such a view.

Pagliari's styptic consists of a strong watery solution of benzoin and alum, which causes instantaneous coagulation of the blood. The clot, however, is less firm than that produced by subsulphate of iron, and I have myself very little confidence in its efficiency as a hemostatic, except in hemorrhage from very small vessels, in which it sometimes answers exceedingly well. A good styptic, often used with great advantage by the late Professor Pancoast, especially in the milder forms of hemorrhage, is composed of one drachm of Venetian soap and twice that quantity of carbonate of potassium dissolved in three ounces of alcohol. Hemorrhage of some of the internal cavities, especially of the uterus, consequent upon the presence of fibrous tumors, is often promptly arrested by the injection of a solution of one drachm of iodine and twice that quantity of iodide of potassium in two ounces of alcohol and four ounces of water. Alcohol alone is not a bad styptic in an oozing wound; it seems to do good by coagulating the albuminoid principles of the blood.

Cold is a powerful styptic, and may be used in various ways. A current of cold air

will often promptly and effectually arrest capillary hemorrhage, or even hemorrhage caused by the division of a small artery, as is exemplified in operations upon the tonsils and anus, or ano-rectal region, as well as upon other parts of the body. To prove beneficial, the air must have free access to the part, and hence it may often be usefully directed by means of the fan, which has the additional advantage of rendering it more cool.

Cold water, refrigerating lotions, pounded ice in bladders, or lumps of ice rolled up in cloths, applied to the bleeding surface or in its immediate vicinity, occasionally promptly arrest hemorrhage. These applications are particularly valuable in deep-seated hemorrhage, or in hemorrhage of the internal organs and cavities; they must, however, be used with a certain degree of caution, as their protracted continuance may be followed by injurious reaction, and even by mortification of the part. When the wound is situated externally, but too deeply to render the injured vessels accessible to the ligature, the bleeding may often be speedily and effectually checked by a full stream of iced water, directed upon the part, and maintained steadily for some time, from a large syringe.

Hot water has lately been found very efficacious in arresting the oozing from wounds, as after amputations, excisions, and the extirpation of tumors. Its beneficial effects are doubtless due to its coagulating effect upon the albumen of the blood, and to its producing contraction of the vessels. It should be applied as hot as can be borne by means of a soft sponge.

The actual cautery can hardly be considered as a genuine styptic, although it is usually classed under this head. Its effect is not to constringe the vessels, but to destroy them, by producing an eschar, by which their mouths are, for the time, hermetically sealed. Upon the separation of the slough, however, there is frequently a recurrence of the hemorrhage, especially if the wounded vessels are at all large, owing to the imperfect coagulation of their contents. The cases to which the cautery is mainly applicable are those in which the hemorrhage proceeds from a deep and narrow osseous cavity, and in wounds of the tonsils, uterus, and rectum. The instrument, which may be of a conical form, should be heated to a black or slightly red heat, and used in such a manner as not to injure the structures around the seat of the affected vessels. When the artery is very diminutive, the object may sometimes be attained with a hot knitting-needle, a wire, or a probe.

General Means.—Whatever mode of procedure be adopted for arresting the bleeding, it is an object of primary importance to place the affected part perfectly at rest, in an easy and elevated position; the slightest motion might be injurious, especially when no ligature has been used, and should, therefore, be sedulously guarded against. Repose of the body is equally necessary with that of the part, and it is hardly needful to add that mental tranquillity is also of the greatest moment. Cardiac action, too, must be maintained in the most perfect quietude, as any perturbating agency of this kind cannot fail to favor a return of the hemorrhage and exhaust the system. With this view, a full anodyne should be administered early in the disease, the dose being repeated from time to time so as to sustain the soothing influence of the remedy. Too much stress cannot be laid upon the use of opiates in the management of arterial hemorrhage, and it is surprising that the remedy is not more generally employed than it seems to be. To allow the heart to go riot, or to move and toss about tumultuously, as it is so liable to do after serious loss of blood, while every local precaution is taken for the suppression of the bleeding, is assuredly a strange inconsistency, and one altogether irreconcilable with experience and common sense. When the bleeding proceeds from a great number of small vessels, a restraining influence may be expected from the administration of ergot in full and repeated doses.

When high constitutional excitement exists, the effect of the anodyne should be aided by the judicious use of aconite or veratrum viride. When the skin is very hot and dry, a full dose of Dover's powder often answers an excellent purpose in calming the heart's action.

The diet should be perfectly bland, and sufficient in quantity to supply the wants of the body. To give less, might cause irritability of the system; to give more, overstimulation. The drink must be cold and acidulated, and not taken so freely as to oppress the stomach, as it will be sure to do if the quantity is not carefully restricted, as the thirst is always urgent after the loss even of a comparatively small amount of blood. Lumps of ice, or pounded ice, held in the mouth, and gradually swallowed, often prove most grateful and beneficial. The air of the apartment must be kept perfectly cool; in short, every effort must be made to maintain the tranquillity of the circulation.

Secondary Hemorrhage.—Secondary hemorrhage occurs at variable periods; sometimes in a few hours, at other times not under several days or weeks. It is not necessarily preceded by primary hemorrhage, but may come on where the loss of blood in the first instance was, perhaps, altogether insignificant, and where everything, so far as this event is concerned, gave promise of a most favorable issue. The bleeding often supervenes without any assignable cause, generally suddenly and unexpectedly; hence it often makes great progress before an opportunity is afforded to arrest it. When proceeding from a large vessel, it may prove fatal in a few minutes, in the same manner as when the bleeding is primary. The scarlet hue of the blood always denotes its source.

The causes of secondary hemorrhage are various, but the most important are the following:—1st. The faulty application of the ligature; 2d. A diseased state of the arteries; 3d. Morbid changes in the clot; 4th. Improper traction upon the ligature; 5th. Tight dressing, or too great dependency of the part; 6th. Want of retraction in the vessels; 7th. Organic lesion of the liver, heart, and other viscera; 8th, scurvy; and, 9th, a hemorrhagic diathesis.

1. When a ligature is properly applied, it simply divides the inner and middle tunics, leaving the outer intact; this too, however may be cut, not completely, but partially, and, therefore, the more insidiously, in consequence of the force used in tying the ligature; or, the deligation may not have been sufficiently firm, the opposite surfaces being only slightly approximated, and the resulting adhesion, therefore, inadequate to effect hermetic closure of the artery on detachment of the cord; or, lastly, the fault may have existed in the ligature itself, on account of the rottenness of its substance, or the imperfect tightening of the knot. Whatever the cause may be, the proper remedy is more efficient ligation.

2. The hemorrhage may arise from disease of the *artery*, either from undue inflammation, or degeneration of its coats, rendering them incapable of supporting the ligature until the clot has contracted sufficiently firm adhesions. The mode of procedure is obvious; a more healthy portion of the vessel must be sought for, and the ligation effected with more caution; or, this failing, the hemorrhage may be arrested by tying the main trunk of the limb, some distance from the seat of the injury. If both these expedients prove unavailing, or if their employment be deemed inadvisable, an attempt should be made to arrest the bleeding by means of styptics, either alone, or in union with a graduated compress and roller. Experience has shown that this method is often far preferable to the ligature, which, under such circumstances, seldom maintains its hold upon the vessel until a sufficient amount of repair has been set up to prevent a recurrence of the hemorrhage.

Fig. 305.

Partial Absorption of the Clot in the Femoral Artery, a Fortnight after Amputation.

3. Morbid changes in the *clot*, commencing in a process of softening and disintegration, occasionally occur after ligation, leading to its premature detachment, perhaps several weeks after the operation. Such changes, which are well illustrated in fig. 305, are most frequent in cases of pyemia and diffused erysipelas, consequent upon some injuries and amputations, eventuating in a tendency to suppurative inflammation. The only remedy is the ligation of a healthy portion of the artery; or, when this is impracticable, the employment of acupressure or the application of styptics and the graduated compress.

4. Surgeons sometimes bring on hemorrhage by improper traction of the *ligature*, with a view of promoting its separation, forgetting that they may thus tear the artery, or break up important adhesions. Such a procedure cannot, as stated elsewhere, be too severely censured. Religation is obviously the remedy in such a case.

5. *Tight dressing*, causing unequal constriction of the part, or improper dependency, favoring undue afflux of blood, may induce this form of hemorrhage. The result will be most likely to occur when a number of small arteries have been divided, without any attempt having been made to secure them with a ligature. Bleeding having ceased, the dressings are applied, but too firmly, or the part is placed too low, and presently blood begins to appear, issuing, perhaps, with great freedom. The treatment consists in the removal and readjustment of the dressing, with strict attention to posture.

6. Secondary hemorrhage occasionally comes on after operations for the relief of anal, perineal, and other fistules, chronic abscesses, and old ulcers, from an inability of the vessels to *retract* in consequence of the indurated condition of the divided

parts. Exposure of the surface to cold air, the application of ice, direct compression, or styptics constitute the best means of relief. In some cases the actual cautery may be required.

7. Organic disease of some of the principal viscera, especially of the liver, heart, and spleen, often favors secondary hemorrhage after injuries and operations. Indeed, spontaneous hemorrhage is by no means uncommon under such circumstances, and it is, therefore, not surprising that it should occasionally occur after accidents and the employment of the knife.

8. *Scurvy* is a powerful predisposing cause of secondary hemorrhage. The blood in this condition of the system is, in great degree, deprived of its coagulability, and hence the clot that forms above the seat of the wound is easily disintegrated and washed away. The coats of the vessel are also softened and diseased, and, therefore, ill able to bear for any length of time the pressure of the ligature, which is generally detached at a period varying from the fifth to the eighth day, before the clot has had time to become firmly adherent to the sides of the affected artery. The most effectual means of counteracting this condition of the system are fresh air, tonics, stimulants, anodynes, vegetable acids, and other antiscorbutic remedies.

9. The bleeding may be due to a *hemorrhagic diathesis*, an affection which, as will be stated elsewhere, may occur at any period of life, and which it is often extremely difficult to control by any mode of treatment, however judiciously conducted.

Finally, this form of hemorrhage is sometimes brought on by *injuries* inflicted in the transportation of the patient, as in time of war and after severe operations, lacerated wounds, and compound fractures. The clot, if not firmly adherent, is easily detached from the jolting of the affected artery and the cardiac excitement consequent upon the disturbance of the part and system. Excessive mental perturbation is capable of producing similar effects, especially when a vessel, previously partially occluded by a clot, has not been properly ligated.

SECT. II.—SUBCUTANEOUS HEMORRHAGE.

There is a form of arterial hemorrhage to which, from its situation, the term subcutaneous is very properly applicable. It takes place when, from any cause, an artery has been laid freely open, and its contents, instead of escaping externally, are extensively extravasated among the surrounding structures. In ordinary hemorrhage, the blood issues directly from the injured vessel, because the outer wound is sufficiently capacious to admit of its free and unrestrained passage, and the consequence, generally, is that it continues until the patient faints, and the bleeding orifice is closed by coagula. In the variety of hemorrhage, however, under consideration, the opening in the integument is so small as to prevent the blood from appearing externally, and it, therefore, accumulates beneath the skin, in the subcutaneous connective tissue when the artery lies superficially, or in the subcutaneous and intermuscular connective tissue when it is deep-seated. The accident which usually causes this hemorrhage is a puncture, such as that inflicted in venesection at the bend of the arm, where, in civil practice, it is most commonly met with. It may, however, in consequence of a stab, the thrust of a bayonet, a gunshot wound, or the laceration occasioned by the sharp end of a broken bone, occur in any part of the body.

The smaller as well as the larger arteries are sometimes ruptured by the passage of the wheel of a carriage, by falls, blows, kicks, and other external injury. The subclavian and axillary arteries have occasionally been lacerated in the attempts to reduce an ancient dislocation of the shoulder-joint. Spontaneous rupture not unfrequently occurs, especially in the arteries of old subjects, in consequence of the degeneration of their tunics, by which they are rendered so brittle as to be incapable of resisting the pressure of the current of the blood. In general, however, the rupture thus induced is partial, or limited to the internal and middle membranes.

The hemorrhage may be very slight, or exceedingly profuse, its extent being regulated chiefly by the size of the affected vessel, and the quantity and laxity of the connective tissue. In the superior extremity, the extravasated fluid often reaches nearly as high up, on the one hand, as the axilla, and, on the other, as low down as the inferior third of the forearm, extensively separating the muscles from each other by breaking up their attachments, and forming a large, ill-shaped, and confused swelling, attended, especially when inflammation sets in, with violent pain, numbness, and œdema of the whole limb, and discoloration of the integument. More or less pulsation is generally present, espe-

cially in the earlier stages of the case, and, upon applying the ear over the site of the wound, a well-marked bruit may frequently be recognized, attended, occasionally, with a peculiar thrill, or a whirring noise, and a vibratory sensation. It is for these reasons that this affection has usually been described as a variety of aneurism: and, as the blood is always widely extravasated, the prefix "diffuse" is commonly added to that term, as particularly expressive of its more important attributes. Strictly speaking, however, there is no aneurism here; there is simply a subcutaneous accumulation of blood, the consequence of external injury, without any dilatation of the vessel, or degeneration of its tunics; and, although there frequently is, as just stated, more or less concomitant pulsation in the part, yet this does not any more entitle it to be regarded as an aneurism than it would be if the effused fluid were so much pus or serum.

The blood that is extravasated in this accident usually promptly coagulates, and exerting injurious compression upon the parts with which it is in contact, soon excites severe inflammation, which, especially in persons of an irritable constitution, is liable to assume an erysipelatous character, and to terminate in suppuration, ulceration, and even gangrene. The pain is often intense, depriving the patient of appetite and sleep, and making rapid inroads upon the system. I have witnessed cases in which, from the excessive distress thus produced, hectic fever soon came on, and life was placed in imminent peril.

The *treatment* of this lesion is precisely similar to that which is necessary when there is an open wound; that is, the artery must be secured promptly and at all hazard, and the coagulated blood thoroughly evacuated. The operation is often one of great embarrassment, owing to the confused and displaced condition of the parts, and the difficulty experienced in finding the injured vessel, which is not unfrequently lost in the midst of the coagulated blood. A large incision is generally required, and two ligatures must be applied, one above and the other below the wound in the vessel, precisely as in ordinary cases, the object being the prevention of hemorrhage by the recurrent circulation. As a preliminary step, the injured artery is compressed by the finger or tourniquet, or, if seated in an extremity, controlled by the elastic bandage, and, after the operation is over, the limb is wrapped up in warm water-dressing, medicated with laudanum and acetate of lead, or laudanum and alcohol, to favor the reduction of inflammation.

SECT. III.—COLLATERAL CIRCULATION.

Among the more interesting phenomena that occur after the deligation of the larger arteries, not the least curious and important is the manner in which the circulation is carried on and maintained in the structures beyond the seat of the ligature. A long time elapsed after the discovery of the ligature before surgeons could be induced to believe that such an operation could be performed in the continuity of a limb without endangering the parts below by gangrene, in consequence of the sudden abstraction of their accustomed supply of blood. Chance gradually led to the correction of this apprehension, which, however, is not without some foundation, as is proved by the fact that the procedure is occasionally followed, even at the present day, in the hands of the most scientific surgeons, by loss of limb and life. Cases had been observed, from time to time, of the obliteration of the largest arterial trunks by fibrinous concretions, and yet it was perfectly certain that the structures in the distal portions of the extremity had retained their normal growth, no difference being discoverable between them and those of the opposite side. Such a result, it was obvious, could only have been brought about by an enlargement of the collateral vessels, thus enabling them to keep up the normal supply of blood, after the obstruction of the main artery. A number of instances had been noticed of complete closure of the aorta, both in its thoracic and abdominal divisions, without any apparent detriment of any kind, either proximate or remote. These facts, the fruits of the cultivation of morbid anatomy, were eminently suggestive, and we accordingly find that they gradually paved the way for some of the most daring feats in surgery. The original trials with the ligature upon the principal arteries in the continuity of the limbs were highly gratifying, as tending to show that, although the distal structures were temporarily deprived of their accustomed supply of blood, this occurrence did not sufficiently interfere with their vitality to cause gangrene, the circulation being speedily reëstablished through the collateral routes. The process employed by nature in effecting this object has been demonstrated, in repeated instances, by dissection of the parts at variable periods after they had been subjected to operation.

The moment a large artery, as, for example, the femoral, is tied, the blood is obliged to seek new channels for its transmission to the distal portion of the limb. For this pur-

pose it passes on in all directions, entering every vessel, both large and small, into which it can find access. This, however, does not occur all at once, but gradually; for as the arteries which are to carry on this collateral circulation, as this arrangement is termed, are comparatively small, some time is necessary to prepare them for the reception and accommodation of the increased flow of blood. In fact, they are compelled to submit to a species of preliminary dilatation, their tonicity being such as rather to resent its encroachment than to yield to its effects. This is the case both with the branches that are detached from the sides of the vessel above the seat of the ligature, and with the capillaries of the various tissues entering into the composition of the limb, which, immediately after such an event, always play an important part in maintaining the distal circulation. Hence, for some time after the operation, the quantity of blood below the point of obstruction is necessarily considerably less than in the normal state, as is demonstrated by the cold and pallid state of the integument, the defective sensibility, and the loss of muscular power, which is occasionally so great as to deprive the patient of motion in the affected member. The diminution of temperature is liable to a good deal of variation, but, in general, it amounts to several degrees, and the surgeon is, therefore, often obliged to employ artificial heat. Gradually, however, as the circulation increases in vigor, the temperature returns to the natural standard, and in many cases even exceeds it, owing to the enlargement and inordinate activity of the cutaneous capillaries, although such an occurrence is usually of short duration.

An instance occasionally occurs in which there is either no change of temperature at all from this cause, or where it is so very slight as to be hardly perceptible. Such a phenomenon is most apt to happen in old aneurisms, where, owing to the obstruction in the artery connected with the tumor, the anastomosing vessels have had time to become enlarged prior to the application of the ligature, so that the operation exerts little, if any, influence upon the circulation in the distal portion of the limb, as it necessarily must in recent cases of that disease, and also in wounds of the arteries, in which no such opportunity is afforded for an increase in the size of the collateral channels.

Coincident with this effort on the part of the affected structures to establish the collateral circulation, there is generally a feeling of uneasiness, if not of actual pain, of a burning or tingling character, obviously occasioned by the compression which the enlarged and distended vessels exert upon the neighboring nerves. Usually, however, this effect is of short duration, as the nerves soon accommodate themselves to their new relations. After some time, the parts gradually recover their natural functions, all disagreeable sensations vanish, the muscles increase in vigor, and the process of nutrition proceeds apparently as well as it did prior to the deligation of the vessel.

Although such is the ordinary course of events after the main artery of a limb has been tied, important exceptions are occasionally met with. Thus, it now and then happens that the circulation remains extremely languid for an unusual length of time, perhaps for a number of days, if not several weeks, the anastomosing branches being seemingly incapable of enlarging to a sufficient extent to convey an adequate supply of blood to the affected structures; the extremity is, consequently, cold, heavy, numb, and of a reddish or purplish hue, from passive congestion of the capillaries, and is moved with pain and difficulty. A struggle is evidently going on between nature and disease, in which the latter but too often comes off victoriously; the limb either falling into gangrene without the occurrence of reaction; or, reaction taking place, it is overpowered by the resulting inflammation. Finally, cases occur, although, fortunately, very unfrequently, in which the parts remain permanently weak and crippled; the muscles are soft and flaccid, the adipose tissue is absorbed, and the surface is habitually cold and congested, the circulation having never attained the normal standard after the operation.

It is worthy of notice that gangrene, from defective circulation, is much less liable to occur after the ligation of an artery, in the continuity of a limb, in wounds than in aneurism. This fact, at all events, is clearly deducible from the statistical tables of Dr. Norris, from which it appears that in seventeen cases in which the femoral artery was secured on account of recent injuries and different tumors, gangrene did not occur in a single one, whereas this result was witnessed in thirty-one cases out of two hundred and four in which the operation was performed for the cure of aneurism. May not the cause of this disparity be the compression which the tumor in this disease exerts upon the neighboring structures, thereby obstructing the circulation in the distal portion of the limb, and at the same time seriously embarrassing the functions of the nerves? I presume that this result is very materially influenced by the nature of the wound, necessitating the deligation of the artery. If, for example, the parts are extensively divided transversely, or very

obliquely, so as to destroy the continuity of a large number of its more important branches in the immediate vicinity of the wound, gangrene will be much more likely to occur than under opposite circumstances, in which, the neighboring vessels being but little injured, the blood will easily find its way into the distal structures, thus affording them the requisite supply not only for the preservation of their vitality, but also for the maintenance of their nutrition.

Although the capillaries are greatly instrumental in carrying on the circulation in the distal portion of the limb, immediately after the deligation of its main artery, their agency is really merely of a temporary character, ceasing with the establishment of the collateral circulation, properly so called, as developed by the larger arterial branches in the vicinity of the ligature. These arterial branches are occasionally given off by the affected artery itself, but most commonly they arise from some neighboring trunks. Thus, when the superficial femoral is tied high up, the collateral circulation is established through the agency mainly of the profunda, the branches of which inosculate with the articular, offsets of the popliteal. In ligation of the brachial, the blood is transmitted to the forearm and hand by the communications naturally existing between the anastomotic and profunda arteries, branches of the affected vessel, and the recurrent branches of the radial and ulnar, in which the brachial terminates. In ligation, on the contrary, of the common carotid, the circulation of the corresponding side of the head and neck is kept up mainly by the communications between the occipital and deep cervical arteries.

It has been noticed, as an interesting physiological fact, that the anastomotic arteries, before they unite with each other, separate into several branches, often as many as three or four, so as to form a kind of circle, as if nature were particularly anxious to guard against any risk that might otherwise occur to the collateral circulation from accident or disease. It has also been noticed, especially by Porta and Stilling, that, when the fibrous structure which connects the two ends of the artery after the detachment of the ligature is unusually short and thick, a narrow, tortuous canal is occasionally developed in its interior, admitting of the passage of blood to the distal portion of the vessel.

However established, the collateral vessels gradually augment in size, until, at length, their united capacity is fully equal to that of the obliterated trunk, as in fig. 306, whatever may have been its size. There are, of course, as already stated, exceptions, but they are, probably, much less frequent than is generally imagined. A very interesting case, beautifully illustrative of the present topic, occurred in the practice of the late Dr. Francis West, of this city, in a stout, athletic man, aged thirty-two, who died suddenly from rupture of an aneurism of the thoracic aorta. On dissection, this vessel was found to be entirely obliterated, just beyond the remains of the arterial duct, its coats having a constricted appearance, as if they had been embraced by a tightly-drawn ligature. Everywhere else, excepting at the place of aneurism, the aorta was perfectly natural. All the branches of the subclavian arteries were much increased in size; and the internal mammary and epigastric, which served to keep up the connection of the circulation above and below the seat of the stricture, were fully as large as the external iliac, the former having coursed along the walls of the chest in a very tortuous manner. As no tumor was discovered at the seat of the obliteration, it could not be determined whether the disease had been the result of accident or of a congenital vice. Be this as it may, the case affords an admirable example of the manner in which the collateral circulation is carried on after the interruption of the column of blood in such an immense vessel as the aorta.

The collateral circulation is not developed with equal facility at all periods of life, or under all circumstances; it is most readily established in young subjects, in whom the arteries, besides being very active, enjoy a high degree of elasticity and pliancy, well adapted for such an enterprise. In old persons, on the contrary, the functional activity of these vessels is often much impaired, many of the small branches are obliterated, and their coats are extremely liable to earthy deposits, converting them into firm, rigid tubes, ill qualified for the discharge of their duties. In many cases, loss of blood, ill-health, or

Fig. 306.

Collateral Circulation shown in the Thigh. At *a*, the Femoral Artery has been Obliterated by Ligature.

defective vital power, seriously interferes with the development of the collateral circulation.

Finally, the collateral circulation may be too active. Such an event is not likely to happen when the main artery of a limb is tied on account of hemorrhage from a wound, but its occurrence is by no means uncommon in aneurism, and is then apt to be followed by a return of the circulation and pulsation in the tumor, in consequence of the activity of the anastomosing branches, which thus continue to feed the sac, and perhaps effectually oppose the cure.

SECT. IV.—HEMORRHAGIC DIATHESIS.

Hæmophilia, or the hemorrhagic diathesis, is that peculiar state of the system in which, generally from some slight traumatic cause, there is a strong tendency to inordinate bleeding. Persons laboring under this constitutional infirmity are often placed in imminent jeopardy by the most insignificant scratch, puncture, or incision, which, under ordinary circumstances, would hardly emit more than a few drops of blood. Occasionally the cause of the bleeding is the accidental rupture of some of the smaller vessels of the mucous membrane of the nose, lungs, rectum, or urinary bladder. The extraction of a tooth is sometimes followed by this form of hemorrhage. I recollect one case in which death was thus produced; and another where the bleeding, having persisted for nearly four days, gave rise to severe exhaustion and great apprehension respecting the safety of the patient. Many years ago I lost a child, six months old, affected with cholera morbus, from hemorrhage consequent upon lancing of the gums over the upper central incisors, which were nearly ready to protrude. His health previously to this attack had always been excellent. The bleeding commenced in less than twenty-four hours after the operation, and continued, despite all that could be done for his relief, until the end of the fifth day, when he died completely exhausted. A short time before he expired, hemorrhagic spots appeared on different parts of the body, and blood began to be discharged from the bowels. In a case of strabismus, in a young gentleman who possessed this peculiarity, the division of the internal straight muscle was followed by an oozing of blood, which continued, despite all I could do, nearly constantly, for the greater part of a fortnight, when, the wound being almost healed, it ceased. In a case reported to the Academy of Surgery of Philadelphia, in 1881, by Dr. John H. Packard, an infant, a fortnight old, died of hemorrhage from a slight scratch of the lip.

The blood in this variety of hemorrhage oozes from the injured part, as water from a sponge; it does not spirt in jets, as when it issues from an artery, or in a continuous stream, as when it flows from a vein. Its color is neither scarlet nor black, but intermediate between the two; it generally partially coagulates when it is received into a vessel, but rarely while it is in contact with the living surface.

This affection has occasionally been noticed in several members of the same family. In a remarkable case, reported by the late Dr. John A. Swett, of New York, it existed in all the children, eighteen in number. All, except one, had died from this cause, and he was suffering under profuse hemorrhage of the nose and rectum. Twelve sisters died before the age of twelve from bleeding of the uterus; and two of the brothers had fallen victims of traumatic hemorrhage.

Mr. Wardrop has reported a curious case in which this peculiarity was hereditary. The patient was a boy, in whom the hemorrhagic tendency displayed itself when he was scarcely two months old. On several occasions he nearly lost his life from the most insignificant wounds. His brother, twenty-two years old, was frequently afflicted in a similar manner. Of his five uncles, not one was free from this predisposition, three having died from the division of the frenum of the tongue, and one from the extraction of a tooth; while the other, although he suffered from the same disease, finally died from some other cause. His two aunts exhibited no signs of this diathesis; but all the male branches of their families, excepting one, were thus affected.

A still more remarkable case has been described by Dr. Hughes, of Kentucky. The predisposition here was associated with the rheumatic diathesis, and was satisfactorily traced as far back as five generations. It was confined exclusively to the male branches of the different families; but the females, nevertheless, invariably transmitted it to their offspring. Many of the individuals died in infancy and childhood, death resulting, in some, from the cut of the lancet; in some, from accidental wounds; in some, from internal hemorrhage; and, in two, simply from the application of blisters, the vesicles being filled with blood instead of water.

Of the remote causes of the hemorrhagic diathesis nothing is known. Whatever they may be, it is evident that they are deeply engrafted in the constitution, as is proved by the fact, first, that the affection generally shows itself at a very early age ; secondly, that it often occurs in several members of the same family ; and, thirdly, that it is sometimes hereditary. The immediate causes seem to be two, want of coagulability in the fibrin of the blood, and an imperfectly organized state of the capillary vessels, the actual seat of the hemorrhage.

If one were inclined to speculate in regard to the cause of this defective coagulating property of the blood, it would be easy to find it in an insufficient supply of nervous power, upon the presence of which, as is well known, the vitality of this fluid essentially depends. Whatever has the effect of weakening this influence, proportionately interferes with the concretion of the blood, both as it circulates through the body and after its removal by venesection. The fact that the blood remains fluid in sudden death from lightning has long been familiar to practitioners. Similar phenomena occur when a person is killed by a blow on the stomach, by prussic acid, the poison of the rattlesnake, excessive bodily fatigue, or violent agitation of the mind. Certain diseases, as Asiatic cholera, plague, and malignant fevers, produce analogous effects. It has been satisfactorily ascertained that, when the pneumogastric nerves are tied in animals, the blood loses its property of coagulating, the coloring matter at the same time separating from the fibrin, and assuming an unusually black color.

But as, in all these cases, the loss of nervous power is sudden, it is easy to perceive how it should influence the coagulation of the blood. In persons laboring under the hemorrhagic diathesis, on the contrary, the blood is generally habitually indisposed to coagulate, so that they are more or less liable to bleeding whenever any injury, however slight, is experienced. The analogy, then, between these different states of the system is exceedingly remote, and can, indeed, hardly be said to be established. Its force, moreover, is weakened by the fact that the subjects of the hemorrhagic diathesis generally enjoy as good health, and as much vigor of constitution, as those who are free from it. The other appreciable element in the pathology of the hemorrhagic diathesis is a want of contractility in the capillary vessels, dependent, in all probability, upon some defective organization and an absence of native tone in the muscular tunic.

The prognosis of this form of hemorrhage is generally not very favorable, particularly when it is of a hereditary nature, in which event it is extremely liable to prove fatal. In the case related by Swett, seventeen out of eighteen members of a family thus affected had perished, and the survivor himself had repeatedly suffered from severe bleeding in different parts of the body. In the case of Hughes, in which the diathesis prevailed in not less than five generations, nearly every individual died from hemorrhage ; many of them in infancy and childhood.

In the *treatment* of the hemorrhagic diathesis, the two leading indications are to promote the coagulability of the blood, and to increase the contractility of the capillary vessels.

The first of these objects is best fulfilled by the judicious use of acetate of lead and opium, the former of which seems to exert a direct influence upon the coagulability of the blood, while the latter affords important aid in controlling the action of the heart, generally rendered turbulent by the bleeding and by the patient's mental anxiety. The dose of the salt should vary from half a grain to a grain and a half, every two, three, or four hours, according to the tolerance of the stomach and the amount of hemorrhage, and should contain at least one grain of opium, or its equivalent of acetate of morphia. If heat and dryness of skin exist, a small quantity of antimony or ipecacuanha may be added to each dose, to promote perspiration. Severe depression, however, must be vigilantly guarded against. Cardiac action is controlled by tincture of aconite or veratrum viride, its effects upon the system being carefully watched.

To increase the contractility of the capillary vessels, ergot must be freely employed, in union with tonics, as tannate of iron and quinine, and a nutritious diet. Dilute sulphuric acid, in doses of eight or ten drops, repeated four or five times a day, is often highly beneficial. The diet should be light and non-stimulant, consisting largely of milk and beef essence, along with more or less alcohol. Tranquillity of mind and body is of paramount importance.

Laxatives usually prove highly serviceable, both as evacuants, as counterirritants, and as restorers of the secretions, which are nearly always much disordered in this variety of hemorrhage. Estimating these remedies at their real value, I am satisfied that they are entitled to the highest rank in the treatment of this affection ; they must not, however,

be carried too far, otherwise they may induce irritability of the heart, and thus do harm instead of good. If the patient is plethoric, sulphate of magnesium may be taken, as it is particularly appropriate, under such circumstances, on account of its chemical action upon the blood; or, what will generally be better, especially when there is marked derangement of the secretions, a few grains of calomel and compound extract of colocynth.

When the bleeding is attended with fever, or with heat and dryness of the surface, diaphoretics, as antimony and morphia, or the neutral mixture, aided by tepid ablutions, are indicated. Coldness of the extremities must be relieved by hot mustard baths and bottles of hot water.

It need hardly be added that the sooner these constitutional measures are carried into effect, the more likely will they be to prove efficient in arresting the hemorrhage; the longer the bleeding has lasted, or the greater the amount of blood lost, the more difficult will it be to arrest the disease and prevent its downward tendency. Moreover, a proper plan of treatment having been selected, it should be diligently persisted in, otherwise it will not be able to exert any beneficial influence, inasmuch as some time must necessarily elapse, in such an affection, before the system can be favorably impressed by any measures, however judicious or energetic.

Topical treatment is generally very essential. When the hemorrhage proceeds from a wound, the affected structures should, if possible, be included in a firm ligature. For this purpose, the twisted suture may be used; or, if this be impracticable, systematic compression may be made by means of a graduated compress, wet with Monsel's solution, and confined with a roller, the surface of the wound having previously been dried, so as to allow the lint to come directly in contact with the bleeding orifices of the divided vessels. Occasionally, the application of pounded ice will restrain the bleeding more effectually than anything else. Rubbing the wound freely with nitrate of silver or sulphate of copper is sometimes useful. The actual cautery, the Vienna paste, and the different acids, have all been recommended when the hemorrhage resists the more ordinary measures; but the objection to them is that, when the eschar drops off, and frequently even before, the bleeding is apt to recur with increased violence. When the blood proceeds from the nose, uterus, or rectum, the most efficient adjuvant is the tampon. Attention to the position of the part is indispensably necessary.

SECT. V.—DISEASES OF THE ARTERIES.

The arteries are liable to inflammation, acute and chronic, suppuration, softening, ulceration, and various kinds of transformations; occlusion is also met with, and is worthy of special consideration, as a cause of gangrene and other mischief.

1. ACUTE INFLAMMATION.

Acute arteritis is generally induced by external injury, or by an extension of disease from adjoining structures. Nevertheless, it occasionally exists as an idiopathic affection, or comes on without any assignable cause, chiefly in persons of a gouty or rheumatic predisposition, from the age of thirty to fifty. Restricted, in the majority of instances, to one or more of the larger trunks, it not unfrequently involves the smaller branches, and sometimes even the capillaries. Occasionally, the malady appears to pervade nearly the whole arterial system.

When arising spontaneously, the disease usually begins in the internal membrane and subserous connective tissue, from which it gradually spreads to the other tunics; the reverse being the case when it is induced by external violence. The anatomical characters of acute arteritis are redness, opacity, rugosity, and softening of the lining membrane, with an engorged, lacerable, and thickened state of the outer and middle coats. When the inflammation is severe, the parietes of the affected artery are generally remarkably pulpy, and so much diminished in consistence as to be easily torn or divided by the ligature. The nutrient vessels are loaded with blood, and often exhibit a veritable varicose aspect, their ultimate twigs ending apparently in the subserous connective tissue. With regard to the redness of the internal membrane, it is liable to considerable diversity; generally speaking, it occurs in small patches, which are diffused over a greater or less extent of surface, and which vary in diameter between that of a split pea and a five-cent piece. In intensity, it ranges from a light pink to a deep scarlet, through numerous intermediate shades of lilac and purple. In some instances the redness is uniform. With this change of color are always associated important alterations of texture. The inner

membrane, losing its smoothness and polish, assumes a rough, fleecy aspect, and, owing to the softened state of the subserous connective tissue, is easily detached from its

Fig. 307.

Fig. 308.

natural connections. Globules of lymph, either alone or blended with pus, occasionally adhere to its inner surface ; and, in the large arteries, it is not uncommon, as seen in figs. 307 and 308, to meet with well-developed pseudo-membranes, similar, in all respects, to those of the serous textures. The other tunics are also much affected, being moist, tumid, friable, and transformed into a reddish, homogeneous mass, almost devoid of cohesive power. Their elasticity, naturally so great, is partially lost, and in many instances they are freely infiltrated with serosity, sanguinolent fluid, or even pure pus. A common occurrence is the formation of fibrinous concretions, closing up the caliber of the affected vessels.

Suppuration of the arteries is probably more frequent than is commonly imagined. The matter being generally formed upon the inner surface of the vessels, is soon swept away by the circulating current, which is, doubtless, the reason why it is not oftener noticed after death. Sometimes, however, it is entangled in the substance of the false membranes, infiltrated into the arterial tissues, or collected into small abscesses between the inner and middle tunics. Arteritis is much less liable to terminate in suppuration than phlebitis, in which respect the one resembles inflammation of the serous membranes, the other of the mucous.

The arteries are almost insusceptible of *gangrene.* Their conservative powers are certainly very great, as is evinced by the fact that they often escape destruction in the midst of parts that are perfectly devitalized. In such cases, their outer surface is incrusted, at an early

Plastic Deposits of the Aorta.

Plastic Plugs occluding the Axillary Artery.

period of the disease, with a thin layer of fibrin ; and, long before the sloughs begin to separate, the blood coagulates in their interior, thus opposing an effectual barrier to the occurrence of hemorrhage.

Softening of the arteries is a common occurrence, especially in the smaller branches. It is often witnessed in organic diseases of the principal viscera, and is a frequent attendant upon acute inflammation, carcinomatous affections, and the application of the ligature. The lesion is characterized, as the name indicates, by a diminution of the cohesive power of the vessels, the coats of which are rendered friable, spongy, and inelastic. It is generally accompanied with slight tumefaction, engorgement of the capillary vessels, and effusion of serosity, or sanguinolent fluid, into the interstitial connective tissue.

The *symptoms* of acute arteritis are generally so obscure as to render it extremely difficult to distinguish it, especially when it occurs in the more deep-seated vessels. In the majority of cases, the attack strongly resembles one of rheumatism. The most reliable phenomena, in a diagnostic point of view, are excessive pain and tenderness along the course of the affected arteries, increased by pressure, cough, and change of posture, and accompanied by violent and tumultuous throbbing, which is sometimes felt over the greater portion of the body, and may often be easily perceived at a considerable distance. The action of the heart is much increased in force and frequency, the pulse is hard, wiry, and thrilling, and the system is disturbed by irritative fever, which rapidly assumes an asthenic type. When the disease is at all extensive, the patient soon succumbs under its influence, the immediate cause of death being either exhaustion from the violence of the inflammation, or from the formation of the fibrinous concretions in the larger arteries, thereby arresting the circulation in some of the more important organs.

There are no symptoms denotive of suppuration, ulceration, or softening of the arteries,

apart from those of acute or chronic inflammation. The formation of matter would probably be ushered in by rigors, followed by copious sweats, hectic irritation, and excessive prostration, but the occurrence would hardly be of so marked a nature as to serve any diagnostic purpose.

Acute arteritis is best treated by the lancet, purgatives, and antimonials, if the patient is young and plethoric, or by a conservative course, if he is weak, decrepit, or exhausted by previous suffering, intemperance, or dissipation. Aconite, veratrum, or colchicum will usually form valuable additions to the other means, especially if they be combined with morphia, which is so necessary to allay pain and quiet the heart's action. If the disease is connected with the rheumatic diathesis, calomel must be given, in full and frequently repeated doses, with a view to early but gentle ptyalism. Colchicum will then also prove useful. The most suitable topical remedies, when the affected arteries are superficial, are leeches, iodine, and saturnine lotions, in union with laudanum.

2. CHRONIC AFFECTIONS.

The most common chronic affections of the arteries are the fibrous, calcareous, and atheromatous transformations, which, although of frequent occurrence, are chiefly interesting in relation to the influence which they exert upon the production of spontaneous aneurism. It is for this reason, therefore, that they should be carefully studied. These transformations, notwithstanding that they widely differ in their physical and chemical properties, possess several characters in common, of which the most important are, first, that they are met with almost exclusively in elderly subjects; secondly, that they render the coats of the vessels brittle, and, consequently, prone to rupture; thirdly, that they nearly always occur in association; and, lastly, that they usually begin in the connective tissue, between the inner and middle tunics, which, however, in time, generally participate in the morbid action.

Fig. 309.

The *fibrous transformation* is characterized by the appearance of small, hard, firm patches beneath the serous layer of the arteries, usually isolated, but sometimes grouped, of no definite shape, thin, and of a whitish, grayish, or pale yellowish aspect. When the patches are numerous or unusually large, they convert the affected arteries into firm, inelastic tubes. The basis matter of this transformation is fibrin, which gradually undergoes the fibroid change.

The *calcareous degeneration*—the calcification of modern writers—is a disease of advanced life, although it has occasionally been noticed in early childhood, and is most common in the aorta and its larger branches, as the iliac, femoral, popliteal, and innominate. The brachial artery is seldom affected. The transformation is comparatively rare in the female; a fact which satisfactorily accounts for the difference in the relative frequency of spontaneous aneurism in the two sexes. An instance occasionally occurs in which there is a strong calcareous diathesis, nearly all the arteries in the body being converted into rigid cylinders. The abnormal matter is deposited in an amorphous form, and is destitute of bone corpuscles; consisting essentially of phosphate and carbonate of lime, in combination with a small quantity of albumen, which apparently serves as its matrix.

The calcareous matter exists in various forms; sometimes in small grains and nodules, now in scales, plates, and patches, and now in complete rings, which, encircling the vessel, convert it into a firm, rigid, inflexible tube, completely destitute of its natural attributes, as seen in fig. 309, from a specimen in my cabinet. The inevitable effect of these changes, which are always most conspicuous in the inner coat, is to render the artery abnormally brittle, and, therefore, ill able to withstand the pressure of its contents.

The starting-point of this deposit is the subserous connective tissue, whence it gradually extends to the inner and middle tunics, both of which are sometimes completely transformed by it. It is rare that the outer coat suffers from it; such a change, however, is not impossible, and I have seen specimens in which the deposit was apparently entirely restricted to it. The exciting cause of the calcareous degeneration is chronic inflammation, as is evinced by the fact that it is invariably accompanied by more or less thickening and induration of the arterial tunics, independently of those produced by the

Calcareous Deposits.

deposit itself. From investigations made a few years ago by Gubler it is highly probable that a strong predisposition to this disorder is established by the constant use of vegetables containing a large percentage of mineral substances, particularly the earthy salts.

The *atheromatous* or fatty degeneration, fig. 310, is very rare among our native inhabitants, but sufficiently common in our immigrants, especially the Irish and English. In

Fig. 310.

Atheromatous Deposits.

Europe, it is said to be more prevalent in Great Britain than in any other country; a fact which accounts for the remarkable frequency of aneurism in that part of the world. The change always begins in the subserous connective substance, generally in minute, isolated points, not larger than the head of a pin, of a pale yellowish, whitish, or brownish color, somewhat greasy to the touch, and of a semiconcrete, friable consistence. In time, many of these points, or dots, coalesce, and so form irregular-shaped patches, which, pushing the lining membrane before them, may involve the whole circumference of the tube, and extend several lines or even inches up and down in the direction of its length. Having remained stationary for an indefinite period, the deposit manifests a disposition to softening and disintegration, and is ultimately converted into a curdy, friable, or, more properly speaking, a pap-like substance, possessing, apparently, all the properties of scrofulous pus. At this stage of the disease, the lining membrane is often elevated into small pustules, or little abscesses, which, bursting, discharge their contents into the blood, thus leaving a corresponding number of ragged and irregular ulcers, cracks, or fissures, the base of which is formed by the middle tunic.
The fatty deposit is most common in the aorta, particularly in its thoracic portion, near the origin of the great cervical trunks. Its occurrence is almost peculiar to the aged. What the causes are, under the influence of which it is developed, has not been ascertained. That it is occasionally connected with imperfect alimentation, and the inordinate use of ardent spirits, is unquestionable, but that these circumstances are essential to its production is not at all probable, as the disease is frequently witnessed in the stoutest and most temperate subjects, a fact which is entirely at variance with such a conclusion.

Under the microscope the atheromatous matter is observed to consist of albuminous and earthy particles, of crystalline plates of cholesterine, of an imperfect fibrous texture,

Fig. 311.

Fatty Granules, with Crystals of Cholesterine, from Atheromatous Deposits in the Aorta.

and of oil globules. The amount of fatty substance is frequently so great that it imparts a greasy stain to paper when dried on it by heat. The minute appearances of this deposit are well shown in fig. 311.

The *amyloid*, or, more properly speaking, albuminoid, degeneration of the coats of the arteries is uncommon in the inhabitants of this country, and little is known respecting the influence which it exerts upon the production of aneurism and the repair of injuries. It always begins in the middle tunic, the cells of which are gradually transformed into compact, pellucid, hyaline particles, the effect of which is to change the affected vessel into a hard, rigid, silvery-looking cord, more or less translucent, and of a clear, glassy appearance, with a lustre not unlike that of rough ice. The deposit upon which the degeneration depends is essentially composed of albumen.

Ulceration, as a consequence of arteritis, whether acute or chronic, is seldom witnessed. Manifesting a peculiar predilection for the larger trunks, it commonly commences in the serous membrane, from which it gradually extends to the middle and outer tunics until it leads to complete perforation. Such a termination, however, is extremely rare. The ulcers, which are very irregular in their form, vary much in size, number, and general character. At times they are very small, scarcely exceeding the diameter of a mustard seed; but they may be as large as a split pea, a five-cent piece, or even a guinea, according to the caliber of the affected tube. Their margins are usually ragged, irregular, and

considerably elevated, but seldom injected ; their bottom, which is rough and uneven, is commonly formed by the middle tunic, the fibres of which frequently present a shreddy, lacerated appearance. In many instances, the erosions look like so many fissures, cracks, or chaps, with sharp, prominent, and irregular borders. This form of the disease is ordinarily dependent upon the presence of calcareous matter. The number of ulcers is seldom considerable, although in a few rare cases the inner surface of the larger trunks has been found completely checkered with them. When confined to the internal tunic, they sometimes admit of cicatrization.

In regard to the different affections now described, there are no remedies which, so far as is at present known, are capable of exerting any influence over their development and cure. What treatment might accomplish, if their diagnosis could be satisfactorily established, is an interesting problem for future inquiry to solve.

3. DISSECTING ANEURISM.

There is an affection of the arteries, occurring exclusively in old persons, more particularly in women, to which the term dissecting aneurism, fig. 312, has been applied : it is not, however, in reality, an aneurism at all, but merely a separation of the lamellæ of the middle tunic, as has been satisfactorily established by the investigations of Dr. Pennock, and by an examination by myself of nearly all the reported cases of the disease. A more appropriate name would be *intraparietal* separation. The lesion, which presents nothing of practical interest, inasmuch as it is always fatal, is entirely limited to the aorta and the larger trunks more immediately connected with it, and is always dependent upon organic disease of the coats of the arteries, rendering them lacerable, and, consequently, incapable of resisting the impulse of the blood. The manner in which the affection takes place is easily understood. In the natural state the different coats are so intimately connected together that it is almost impossible, even by the nicest dissection, to detach them from each other; but when they are altered by disease, or by some of the degenerations to which they are so liable, the connective tissue is rendered soft and friable, and their separation may then be very easily effected. In this condition, moreover, the tunics themselves are frequently very much changed, so that they are scarcely able to resist the slightest impulse. Now, if under these circumstances the lining membrane gives way, whether from ulceration, erosion, or rupture, the blood insinuates itself into the accidental opening, which is thus gradually enlarged, at the same time that the fluid is forced on between the layers of the weakened middle tunic,

Fig. 312.

The so-called Dissecting Aneurism. *a*, Semilunar Valves ; *b*, External Vessel laid open in its entire Extent, so as to Expose the Aorta at *c* ; *d*, Valvular Opening in the Coats of the Aorta, showing the Communication of this Vessel with the Artificial Channel, *b* ; the Probe *e* passed through the Abnormal Opening ; *f* exhibits the Foramina between the Aorta and the Outer Canal.

dissecting them from each other as with a knife, and forming thus either a blind pouch or a distinct canal, open at both extremities, or at some intermediate point.

The separation rarely embraces more than one-fourth, one-half, or two-thirds of the circumference of the tube, while in length it may vary from six, eight, or ten lines to as many inches. Occasionally it reaches nearly from one extremity of the aorta to the other, being, perhaps, prolonged at the same time into the carotid, subclavian, and iliac arteries.

4. VARICOSE ENLARGEMENT.

The arteries are liable to a dilated and nodulated condition, similar to that of the veins, and hence very frequently termed varicose enlargement. The affection has also been described under the name of cirsoid aneurism, or arterial varix. Its general features are well illustrated in fig. 313. The lesion, which is exceedingly rare, is met with chiefly in

the superficial arteries, particularly in those about the hand, forearm, leg, and foot ; and consists in a remarkably tortuous, elongated, and convoluted state of these vessels, evidently dependent upon the effects of inflammatory action, as is shown by the fact that their coats are always abnormally thickened, either uniformly, or alternately thickened

Fig. 313.

Varicose Enlargement of the Arteries of the Hand.

and attenuated.   In elderly subjects it is generally associated with the fibro-cartilaginous, earthy, or fatty degeneration.   The dilatation and varicosity sometimes affect an entire artery, but more commonly they are limited to particular portions of it ; they may be restricted to one vessel, or occur simultaneously in several.   When the diseased artery is superficial, the character of the lesion is rendered sufficiently clear by the tortuous and nodulated course of the vessel beneath the surface ; but there are no pathognomonic signs when it is deep-seated.

This affection rarely requires any treatment ; for, even when the enlargement is considerable, it is rather an inconvenience than an actual disease.   In ordinary cases, the vessels may be supported by the constant use of a well-applied bandage, or of an apparatus constructed upon the principle of the laced stocking.   During the forming stage, much may be done in the way of repressing development by astringent and soothing lotions, along with rest and elevation of the parts, and the occasional abstraction of blood, provided the patient is plethoric, in order to moderate the momentum of the circulation. When the disease proves troublesome, by causing pain and functional disorder, the only effectual remedy is ligation of the offending vessels, at the cardiac side of the enlargement.

5. OCCLUSION.

Accidental occlusion of the arteries was long ago noticed by pathologists, but its great practical importance was not fully appreciated until within a comparatively recent period. One form of gangrene, the senile, so graphically described by Pott, has long been known as one of its principal effects.

The causes of accidental occlusion are various.   The most important are, 1st, acute inflammation ; 2dly, the atheromatous and calcareous degeneration of the coats of the vessels ; 3dly, embolism, or the formation of clots ; 4thly, fibrinous concretions; 5thly, morbid vegetations ; 6thly, pressure of the ends of fractured bones ; 7thly, exuberant callus ; and, lastly, different kinds of tumors, soft, hard, and aneurismal.

The effects of acute arteritis and the atheromatous and calcareous degenerations of the coats of the arteries upon the circulation have already been considered under the respective heads of those maladies.   Such changes, which are most common in the aorta and its larger branches, and in the arteries of the inferior extremities, are very liable to be followed by the formation of clots and fibrinous concretions, by which the caliber of the vessels is obstructed and the nutrition of the parts supplied by them materially impaired, if not completely interrupted.   Embolism, properly so called, acts precisely in a similar manner.   Clots are liable to form in all arteries, large as well as small, often suddenly and unexpectedly, and followed by the worst results, both local and general. Inflammation of the lining membrane of the arteries, attended with a deposit of plasma, is generally the exciting cause of embolism, the blood as it sweeps over the affected surface becoming adherent to it, and thus acting as a nucleus around which the fluids concrete.   Embolism has been noticed in all the principal organs of the body, as well as in all the main arteries of the extremities, especially the lower.   Fibrinous concretions

are sometimes detached from the interior of an aneurism, and, being transmitted into the distal portion of the diseased artery, effectually arrest its circulation. The valves of the heart in gouty and rheumatic affections are liable to be studded with morbid vegetations, which, being accidentally detached, occasion obstruction in the arteries, often followed by gangrene and other grave effects. These vegetations may, like the clots in embolism, be transported by the sanguineous current to remote parts of the body, and thus cause occlusion and disease in vessels up to that period in a perfectly sound condition.

An artery compressed by the projecting end of a broken bone is sometimes occluded in its distal extremity as completely as if it had been embraced by a ligature. Similar effects may be produced by the pressure of exuberant callus, of an exostosis, and of fibrous and other morbid growths. Under such circumstances, however, the obstruction usually occurs slowly, not rapidly or suddenly, as when it is caused by the projecting extremity of a fractured bone. The pressure of an aneurism may lead to occlusion of the distal arteries, as is occasionally witnessed in popliteal aneurism, the effect of which is to block up the arteries of the leg and to bring about gangrene in the unnourished structures.

Embolism, however induced, is not peculiar to any period of life, although it is unquestionably most common in the aged. This, however, is true mainly of the chronic form of the affection; for the acute, if so it may be termed, or that which arises suddenly, is not unfrequently met with in very young subjects, and even in children and infants, although such an occurrence is very infrequent.

The most common effect of accidental occlusion of the arteries is gangrene in the structures below the seat of the obstruction. Such an occurrence is almost a necessary and inevitable consequence of sudden obstruction; in chronic cases, on the contrary, the circulation may be maintained by the collateral vessels, and the clots be even ultimately absorbed, although such a termination is very uncommon. Instantaneous death may be produced when a clot suddenly finds its way into the heart, the mouth of the aorta, the lung, or the brain. Organs supplied by a single artery, as the retina and testicle, lose their function and fall into a state of atrophy when their circulation is thus cut off.

The *symptoms* denotive of arterial occlusion are generally so obscure as to render the diagnosis exceedingly difficult, if not impossible, in the earlier stages of the occurrence. Obstruction of the trunks of the extremities is usually attended by a sense of numbness and tingling along the course of the principal vessels, rapidly followed by tenderness and pain, both of which are often extremely violent. The skin, at first pale, soon becomes purple, and then mottled; temperature, motion, and sensation are diminished, and the impoverished structures are finally seized with gangrene. Sometimes the pain is of a wandering character, very much as in gout or rheumatism; and cases occur, although rarely, in which it is perceived at distant parts of the body. More or less fever generally attends, and the system, in most cases, speedily sinks into a typhoid condition. Children and young subjects commonly bear up better under arterial occlusion than elderly persons, few of whom recover. Acute occlusion is more dangerous to life than chronic, and is generally more rapidly fatal.

The *treatment* of arterial occlusion is unsatisfactory. In general, little can be done beyond attention to the posture of the limb, and the preservation of its temperature by means of cotton and flannel, the relief of pain by anodynes, and the maintenance of the strength by suitable food and drink. Moist applications are usually hurtful. When gangrene arises, the object should be to promote the separation of the sloughs, and to prevent fetor by the liberal use of deodorizers, fresh air, and rigid attention to cleanliness. Amputation is seldom proper, especially in chronic cases, even when a distinct line of demarcation exists, experience having shown that, unless the patient possesses uncommon constitutional vigor, the operation generally proves fatal. Now and then there is, of course, an exception, but death is unquestionably the rule. In the acute form of the affection amputation sometimes succeeds in saving life, provided there is a well-formed line between the dead and living structures, with a good state of the system, and perfect exemption from internal complications.

SECT. VI.—ANEURISM.

An aneurism may be defined to be a pulsating tumor, occupied by blood, and communicating with an artery deprived, either partly or completely, of its integrity.

The subject of aneurism has been encumbered by too many divisions and subdivisions, and the consequence is that several lesions have been included under it which do not, properly speaking, appertain to it. The effect of this overrefinement has been to embarrass the study of this disease, and to invest it with difficulties which are altogether foreign to it. The distinction of aneurism into true and false is one of great importance, and should, therefore, be retained. The same may be said in regard to spontaneous and traumatic aneurism. The term dissecting aneurism, introduced by Laennec, and adopted by most modern authors, should be discarded, inasmuch as the affection which it serves to designate has nothing whatever in common with aneurism; it is, in fact, as already stated, merely a separation of the coats of the arteries, without any tumor or symptoms denotive of that lesion. Then again, as to the term varicose, which I have myself, along with others, employed, in my writings, to designate a peculiar form of arterial lesion, it is obviously improper when we come to make a practical application of it. A varicose artery is, in reality, no more an aneurism than a varicose vein; both affections consist essentially in a dilated and tortuous state of these two classes of vessels, and not, as an aneurism, in a pulsating tumor, caused by the destruction, partial or complete, of the tunics of an artery. An anastomotic aneurism is a pulsating tumor formed by hypertrophy of the arterial and venous capillaries of a part; critically speaking, therefore, the term aneurism is not applicable to it, and yet, as it has been fully engrafted upon our surgical nomenclature, it is difficult to dispense with it, or to substitute one of a more expressive and appropriate character.

The term true is applied to that species of aneurism in which one or more of the arterial tunics, without being necessarily perfect, form a part of the tumor. In a false aneurism, on the contrary, all the coats have given way, and the sac is composed of condensed connective tissue. It was formerly supposed, chiefly through the influence of the writings of Scarpa, that there was no such disease as a true aneurism, but that in every instance, whatever might be the size, form, or site of the tumor, there was a complete absence of the arterial tunics. This opinion, however, has become obsolete, experience having shown that there are cases, although they are confessedly rare, in which the aneurism clearly consists of at least one, if not more, of the coats of the artery from which it springs. Each of these great divisions comprises several varieties, founded principally upon the form and volume of the tumor. Thus, an aneurism is said to be sacculated when it consists of a distinct pouch, as so often happens in aneurism of the aorta and its principal branches; the term cylindroid is used when the swelling affects the artery uniformly in its entire circumference, while the tapering tumor is known by the appellation of fusiform. The words circumscribed and diffused refer mainly to the dimensions of the aneurism.

Fig. 314.

Fig. 315.

Fig. 316.

Fig. 317.

The annexed sketches afford a good idea of the arrangement of the tunics of the arteries in the principal varieties of spontaneous aneurism. In fig. 314 the tumor is formed by the expansion of all the coats of the vessel, an extremely rare event; in fig. 315 the middle tunic has given way, the inner and outer being preserved; in fig. 316 the aneurism is formed by the external tunic alone; in fig. 317 the two outer membranes have been ruptured, the inner projecting through the crevice thus left in the form of a hernia. This variety is very uncommon, but cases of it have been reported by different authors, especially by Haller, Laennec, Dupuytren, and Dubois. It can occur only when the inner coat of the artery has been thickened and fortified by interstitial and surfacial deposits.

Finally, aneurisms are divided into internal and external, the former expression being used chiefly in reference to the aorta and to the arteries of the viscera, the latter in relation to the vessels of the head, neck, and extremities. The words spontaneous and traumatic sufficiently explain themselves.

1. LOCALITY, PREVALENCE, AGE, SEX, AND CAUSES.

Spontaneous aneurism does not occur with equal frequency in all parts of the body; on the contrary, there are a number of arteries which are almost entirely exempt from it, or
which, at all events, so seldom suffer as to be scarcely entitled to notice. The vessel which is most frequently involved is the aorta; first in its ascending portion, then in the thoracic, and lastly in the abdominal. Next in point of liability to the disease are the popliteal artery, the femoral, common carotid, subclavian, innominate, axillary, and external iliac. The arteries of the leg and foot, hand, forearm and arm, face, upper part of the neck, and of the viscera, together with the common and internal iliac, rarely suffer in this wise. Traumatic aneurism may occur in any of the arteries, but is most common in those that are most exposed to external injury.

Of the causes which induce spontaneous aneurism more frequently in one artery than in another, nothing definite is ascertained. Several circumstances, however, may be assigned as affording at least a plausible explanation of the circumstance.

1. It is well known that certain arteries are peculiarly prone to the calcareous and atheromatous degenerations, while others are almost entirely exempt from them, whatever may be the condition of the rest of the arterial system, or the age of the patient. Now, dissection has shown that those vessels which are most frequently diseased in this way are also those which are most frequently affected with aneurism, and conversely. Spontaneous aneurism of the arm and forearm is among the rarest occurrences, and everybody knows how free their vessels are from the degenerations in question. In the aorta and popliteal artery, on the other hand, they are extremely common, and it is here, as already seen, that spontaneous aneurism is most frequent.

2. In the next place, some influence is no doubt due, in the production of this difference, to the force with which the blood impinges against the walls of the vessels. Thus, in the aorta, which is more prone to aneurism than any other artery, the ascending portion, particularly its anterior and right side, suffers more frequently than any other part, and it is here that the blood exerts its greatest force, as it is pumped up from the left ventricle. The popliteal artery, which comes next in the order of involvement, is subjected, in a degree beyond that of any other vessel in the extremities, to a similiar influence during the flexed condition of the limb.

3. It is not improbable that some influence is also due to the weakness which the arteries experience at the origin of their larger branches. The fibres of the middle tunic suffer a species of separation here, in consequence of which they are less capable of withstanding the shock of the blood as it is directed against them. However this may be, experience teaches that aneurism is peculiarly liable to occur at these points.

4. Another circumstance which may be supposed to favor the production of aneurism is the motion to which the arteries are subjected, especially during sudden and violent efforts. Such an influence must be particularly felt by the ascending portion of the aorta during bodily and mental excitement, and by the popliteal artery in the various muscular exertions of the lower extremity.

How far any one of these causes alone is capable of producing aneurism is altogether a matter of conjecture. Without degeneration of the arterial tunics, they would probably exert but little influence, while under opposite circumstances it must be very great. Indeed, it is very questionable whether aneurism would be the one-twentieth part as common as it is, if the arteries were exempt from the earthy and atheromatous deposits; nay, we may go further, and assert, positively, that if these deposits could be prevented, spontaneous aneurism would almost cease to exist.

The occurrence of aneurism would seem to be influenced by climate or *locality*. The infrequency of the lesion in the inhabitants of the southwestern States of North America is proverbial. In an extensive practice in Ohio and Kentucky of twenty-three years, I rarely met with an example of spontaneous aneurism; and my experience, in this respect, is fully borne out by that of the late Dr. Dudley, of Lexington, whose practice embraced a wide field, afterwards so successfully cultivated by Professor James B. Bush. The testimony of other western and southwestern surgeons is precisely of the same import. To what this extraordinary immunity is due, we have no means of determining. The population of those regions of the United States is a mixed and laborious one, made up from all parts of the civilized world, and pursuing all kinds of occupations, from the most delicate and refined to the most rude and vigorous, and yet a case of spontaneous aneurism, in any class of its citizens, is absolutely an anomaly. The disease, if I mistake not, is equally uncommon in our northern and middle States.

In regard to the prevalence of aneurism in our larger towns and cities, our information is very imperfect. Professor Gibson, formerly of the University of Pennsylvania, asserts that the disease is very uncommon in Philadelphia, and this I know to be the fact from the results of my own observations. In New York, on the contrary, it would seem,

according to the statement of Dr. Mott, to be quite frequent; a circumstance which is, perhaps, not surprising, when we consider the heterogeneous character of the people of that city, and, above all, the extent of its commerce, and the numerous accidents incident to its pursuits. What is remarkable, however, is, that all the cases met with by this distinguished surgeon, during a period of nearly forty years, occurred among native-born citizens of the United States. In opposition to this fact, however, I have the authority of Dr. John Watson and others, of New York—as communicated to me by Dr. Lente—for stating that the great majority of cases of aneurism in that city, especially in hospital practice, are met with among those of foreign birth. Its negroes would also seem to be particularly liable to the disease.

Aneurism is uncommon in the East and West Indies, in the British Provinces of North America, and on the continent of Europe, especially in France, Italy, and Germany. In Great Britian, on the contrary, it is sufficiently frequent; more so, perhaps, than in any other part of the globe. According to the report of the registrar-general, it appears that the number of deaths from aneurism, in England and Wales alone, during a period of five years—namely, from 1838 to 1842—was 593; being an annual average of one in about 131,000 of the inhabitants. The various hospitals of London receive every year a large number of cases of this disease. The people of Ireland are said to suffer more frequently from aneurism than any other race. In Egypt aneurism is almost unknown.

The *causes* of aneurism are predisposing and exciting. Of the former, the most constant, and, therefore, the most important, is a diseased condition of the arterial tissues, usually in the form of the earthy or atheromatous degeneration. These degenerations, by rendering the coats of these vessels preternaturally brittle and lacerable, induce them to yield more readily under the impulse of the blood and the various extraneous circumstances which have a tendency to stretch and twist them. I have already expressed the belief that, but for these alterations, spontaneous aneurism would be almost unknown. All laborious pursuits, involving sudden and violent muscular exertion, powerfully predispose to its occurrence. Hence, it is more common among sailors, and those who are much accustomed to athletic exercises, than among any other classes of individuals. Soldiers suffer much less frequently than was formerly supposed. Men engaged in agricultural pursuits, although their labor is often severe, are, in great measure, free from the disease, owing to the fact that their arteries are singularly exempt from the calcareous and atheromatous degenerations. Popliteal and femoral aneurism used to be sufficiently common in Great Britain among post-boys, but their frequency, according to Dr. P. H. Watson, has much diminished since the introduction of railroads has replaced this class of persons. Protracted courses of mercury, a syphilitic taint of the system, and the constant and inordinate use of ardent spirits, are supposed to predispose to the formation of aneurism; but how far, or in what degree, remains to be demonstrated.

Embolism is an occasional cause of aneurism, especially of the popliteal artery, producing first obstruction of the caliber of the vessel, and then softening and expansion of its coats. Traumatic aneurism, as the name implies, is the result of external injury, as various kinds of wounds, incised, lacerated, punctured, and gunshot. Roux has reported a case in which an aneurism of the axillary artery was produced by the pressure of an exostosis; and Dr. Thomas, of Closmadeuc, met with a similar occurrence in the popliteal artery. Dr. Castle, of New York, saw a case in which the disease was developed in the palatine artery by the pressure of the plate of a set of artificial teeth.

The formation of aneurism is remarkably influenced by age. Prior to the thirtieth year the disease is extremely rare, and up to the period of puberty it is almost unknown, even in the aorta, which is so much more frequently affected than the other vessels. The greatest number of cases, by far, occur between the thirty-fifth and fiftieth years; a good many cases are also met with during the next decennial period and a half, but after that time the malady is very rare; probably not that the predisposition to it ceases, but because, as it seems to me, in the first place, the number of subjects is comparatively small; and, secondly, because persons at this age are much less exposed to violent muscular and mental excitement than during the meridian of life. That this supposition is true is rendered highly probable by the fact that the earthy and atheromatous deposits generally exist in greatest abundance in advanced life. The absence of these deposits in young subjects readily explains the rarity of aneurism in children and adolescents.

Although spontaneous aneurism in early life is very uncommon, examples have been noticed by different observers, all, apparently, referable to the effects of embolism. Mr. Syme, in 1844, operated upon a boy for a popliteal aneurism that had made its appearance at the age of seven years; and he alludes to two other instances in which the disease occurred

in children.   Sir Astley Cooper met with it in the anterior tibial artery at the age of eleven years; Mr. Hutchinson, in the arch of the aorta at four; Mr. Armitage, in the abdominal aorta at seven and a half; and Dr. Ogle, in the ulnar artery at seventeen. Dr. W. S. Church, of London, has published a table of thirteen cases of intracranial aneurism occurring in subjects under twenty years of age.

The immediate cause of aneurism is rupture of the coats of the arteries, in consequence of severe muscular exertion unduly stretching these vessels; or, as in the case of the aorta and its larger offsets, an inordinate impulse of the blood, during the sudden and violent contraction of the left ventricle of the heart.   The vessels, weakened by chronic inflammation and the degeneration of their tissues, and deprived of their elasticity, readily yield to the forces thus applied, commonly at a particular point, which is afterwards converted into a distinct pulsating tumor, generally composed, in great measure, if not exclusively, of the external tunic of the artery, along with more or less of the circumjacent connective tissue.   Sometimes the exciting cause of the disease is ulceration, but such an occurrence is comparatively rare, especially as an affection independent of the earthy and atheromatous deposits.   The process, as stated in a previous section, should not be confounded with the cracks or fissures which so often follow upon these deposits, inasmuch as the latter are usually the result, not of a vital action, as in true ulceration, but of a mere mechanical one, gradually effected under the impulse of the blood, as it rushes over the inner coat of the diseased vessel.

Aneurism occasionally exists simultaneously in several arteries.   Thus, it is by no means uncommon for a patient to have one tumor of this kind in the aorta, and another in the carotid, subclavian, popliteal, femoral, or external iliac artery.   I have seen several instances of the coexistence of popliteal aneurism on both sides in the same individual. When the disease affects a considerable number of arteries, it constitutes what is termed the *aneurismal diathesis;* a circumstance which, as a rule, imperatively contraindicates surgical interference, however favorably the external tumor may be situated for operation. Weak, sickly persons, of depraved constitution, and intemperate habits, are the most common subjects of this diathesis.   Several remarkable examples of this predisposition to the formation of aneurism are upon record.   Pelletan gives one in which the number of tumors was upwards of sixty, and in another, related by J. Cloquet, there were more than two hundred, the patient being a man fifty years of age.   The aneurisms, in this instance, affected nearly all the arteries in the body, but they were most numerous in those of the extremities, the axillary, brachial, radial, ulnar, femoral, popliteal, tibial, and peroneal being all closely studded with them.

Sometimes two aneurisms form in close proximity with each other; and, the fact not being recognized beforehand, may, in the event of an operation, cause so much embarrassment in the attempt to pass the ligature as to necessitate its abandonment.

Men suffer from aneurism more frequently than women, but in what precise proportion is not determined.   The question has hitherto engaged but little attention, and it is obvious that it can only be decided by the analysis of a much larger number of cases than have yet been adduced for the purpose.   It has been alleged that the relative frequency of carotid aneurism in the two sexes is nearly equal, and the occurrence has been attempted to be accounted for on the supposition that the arteries of the neck of the female are nearly as much exposed to all kinds of violence and muscular exertion as those of the male. Little confidence, however, can be placed in such opinions; for, before we can receive them as true, we must be satisfied that the disease is as common in women as in men, which I am very certain it is not.   The statistics of Mr. Crisp show that of 551 cases of aneurism of all kinds, more than seven-eighths occurred in men.

Having long been impressed with the belief, founded upon numerous dissections, that the difference in the relative frequency of aneurism in the two sexes was due, not to any difference in their occupation, but to the difference in the relative frequency of the earthy and fatty degenerations of the arteries, I was induced to institute a special inquiry into the subject, and am gratified to be able to say that my views are fully confirmed by the statements of Professor Agnew, Dr. C. E. Isaacs, T. G. Richardson, and J. B. S. Jackson.   The testimony of these teachers, all well known as able and experienced practical anatomists, tends to show, indisputably, that females are much less subject to chronic disease of the arteries of every description than males.   Neither their information, however, nor my own, is such as to enable me to determine the relative proportion of these degenerations in the two sexes, in a given number of cases; but that it corresponds very closely with the difference in the number of cases of aneurism is, I think, fully established.

If what is here said be true, it follows that the opinion which ascribes the greater fre-

quency of spontaneous aneurism in males than in females to their more laborious occupation, their more intemperate habits, and their greater exposure to all kinds of disease, is entirely untenable, and, therefore, unworthy of confidence. Women, it is true, are not sailors, carpenters, blacksmiths, or hod-carriers, but in many parts of the world they are tillers of the soil, and engaged in almost every variety of pursuit calculated to rupture the arterial tunics if they were in a serious state of disease, such as we so often meet with in the other sex.

2. VARIETIES OF ANEURISM.

True aneurism presents itself under two varieties of form, differing from each other materially in their appearance and mode of formation, although their essential symptoms and effects are usually perfectly similar, if not identical. These two varieties are the tubular and the sacciform, terms which are sufficiently expressive of their general confor-

Fig. 318.

Sacculated Aneurism.

mation. Each consists of one or more of the arterial tunics, and forms a tumor, which, in time, is capable of exerting the most injurious effects upon the neighboring structures, and of causing the death of the patient. The diffused aneurism, properly so called, is always the result of a diseased condition of the circumscribed, especially of the sacculated.
The *sacciform variety*, fig. 318, is by far the more common of the two. It essentially consists, as the name denotes, in the formation of a pouch, bag, or sac, connected with the side of the affected artery. In the tubular variety the tumor is formed at the expense of the entire circumference of the vessel; in this, on the contrary, it occupies only a limited portion of it. The arteries most liable to sacciform aneurism are the aorta, particularly its thoracic division, the popliteal, femoral, innominate, carotid, and subclavian. The number of tumors is subject to considerable diversity; cases have been reported in which there were so many as to constitute a genuine aneurismal diathesis, nearly all the principal arteries in the body being more or less implicated. In general, however, there is only one, although others may be developed during its progress. Thus, it occasionally happens in popliteal aneurism that an aneurism forms in the aorta, the carotid, or in the popliteal artery of the opposite side.

The sacciform aneurism is capable of assuming a great variety of forms; the most common is the globular or ovoidal; in rare cases it is conical, elongated, or irregularly flattened, like a shot-pouch. Much diversity also obtains in regard to its dimensions; thus, while in some instances it is hardly of the volume of a hazelnut, in others it is as large as a fist, or the head of the patient; in general, however, it does not exceed a hen's egg, or a medium-sized orange. The largest aneurisms of this kind are usually found in the aorta, and in the popliteal, iliac, and innominate arteries. The attachment of the

Fig. 319.
Aneurism of the Aorta: the greater part of the Sac being filled with clots, and the Aperture of Communication being small.

tumor to the artery is commonly effected by a narrow footstalk; but cases occur in which it takes place by a broad and extended base, and it is then not unusual for the artery to suffer serious compression during the progress of the disease.

The orifice of communication, fig. 319, between the sac and the artery varies in different preparations. When the tumor arises by a narrow footstalk, the opening is usually proportionately small, with smooth and well-defined margins. When, on the other hand, it is attached by a broad base, the aperture is always much larger, and its edges are also more irregular, sometimes, indeed, quite shreddy and ragged, as if they had been torn. The situation of the orifice is commonly towards the centre of the sac but it may be at one side, or even at one of its extremities. The form of the opening is extremely variable, and admits of no specific description. In the early stage

of the disease, and in nearly all cases where the tumor is small, the orifice is of a rounded or circular configuration, while in cases of an opposite character it is generally more or less irregular. The internal and middle tunics may terminate abruptly at the margins of the opening of communication, or they may extend into the cavity of the sac, and thus serve to give it a partial lining.

The sac generally consists simply of the external tunic, the inner and middle having given way either prior to, or during, the development of the disease. The first thing, in fact, that commonly happens, in all such cases, is the destruction, by ulceration or some other disorder, first, of the internal, and, soon after, of the middle layer of the artery, leaving thus a kind of crevice, which gradually enlarges under the influence of the impelling column of blood, and thus permits the corresponding portion of the vessel, now, of course, greatly weakened, to be converted into a pouch. This pouch, usually called the aneurismal sac, is then originally composed exclusively of the external coat of the affected vessel, the other strata terminating abruptly at the margin of the opening of communication, neither of them being prolonged into its interior. But this pouch would be very weak, and, consequently, ill adapted to withstand the shock of the blood as it rushes into its interior, if it were not strengthened by adventitious aid, derived from interstitial deposits in the surrounding connective tissue. We accordingly find that nature, ever on the alert to save the part and system, is prompt in supplying the required relief by setting up inflammation and pouring out plastic matter, both in the substance of the sac and in the neighboring structures, thereby thoroughly gluing them together, at the same time that they are greatly increased in thickness and density, and thus enabled more effectually to resist the effects of the ever-beating, dashing, and tumultuous sanguineous current within. Such aid, then, is wise and needful, and, fortunately, always comes in play at an early stage of the disease, the laceration of the inner and middle tunics of the artery, and the pressure of the blood against the tumor, being sufficient causes of inflammation. When the periosteum contributes to the formation of the sac, as it occasionally does in aneurism of the thoracic aorta, the walls of the tumor may be partly earthy, or even partly osseous.

Although the sac is generally composed of the outer tunic alone, cases, nevertheless, occasionally occur where it consists, in the first instance, exclusively of the inner coat, the other two having given way. That such an arrangement is exceedingly infrequent, is proved by the fact that many surgeons of large experience have warmly contested the possibility of its existence. Haller and his contemporaries, however, met with undoubted cases of it, and, in more recent times, it has been witnessed by Breschet, Dupuytren, and other observers, who have given particular descriptions of it. One ground for assuming that this form of aneurism cannot occur, is that it has never followed the numerous attempts that have been made to produce it in the inferior animals, by exposing the carotid artery and dissecting off its outer and middle tunics. In every experiment of this kind, the denuded membrane maintained its integrity, and the breach was speedily repaired by a free deposit of plastic matter. There is, however, no analogy between a sound and a diseased artery, and this fact should be borne in mind in the discussion of the subject. When the outer and middle tunics are destroyed by ulceration, as they always must be in such a case, not rapidly, but slowly, it is not difficult to suppose that the inner membrane may, at the injured and weakened part of the vessel, be made to bulge across the opening, in the form of a thin, translucent cyst. Interstitial deposits would soon aid in strengthening the cyst, although ere long, and before it has acquired any considerable bulk, it would be obliged to yield to the resistless impulse of the blood within. Haller has described this variety of aneurism under the term hernia of the inner coat of the arteries.

Cases in which the sac consists of the outer and inner coats of the artery, the middle having been destroyed, although also exceedingly infrequent, are more common than those in which it consists of the internal tunic alone. Such an arrangement is occasionally observed in aneurism of the carotid, femoral, and popliteal arteries; but, in time, the lining membrane is sure to give way, leaving thus the cyst composed of the outer coat and of the surrounding tissues, as in the ordinary form of sacculated aneurism.

The sac varies in thickness in different cases and under different circumstances, from the fourth of a line to the fourth of an inch. It is often remarkably tough, and, in cases of long standing, it is generally composed of several distinct strata, of a grayish, whitish, or drab-colored aspect, consisting of fibres which intersect each other in every conceivable direction. The outer surface of the tumor is rough and shreddy; the internal,

on the contrary, is smooth and polished, only, however, as a general rule, in its earlier stages, for in time it also becomes rough, and is finally incrusted with fibrinous matter.

Fig. 320.

Sacciform Aneurism of the Aorta ready to give way.

Notwithstanding the thickness of the aneurismal sac, and the efforts which nature makes to strengthen it, it gradually dilates, as in fig. 320, under the impulse of the inflowing column of blood, and at length, after the lapse, perhaps, of several months, manifests a disposition to yield at one or more points, very much as an abscess, the activity of the absorbent vessels exceeding that of the capillary.

The sacciform aneurism always contains, even at an early period of its formation, *fibrinous concretions*, the presence of which constitutes one of its most interesting and important features, as they are evidently designed not only to strengthen the tumor, but to aid in its obliteration, and, consequently, in the production of a permanent cure, although such an event is extremely rare. In their arrangement, these clots are always concentric, not unlike the layers of an onion, one being piled upon, and closely connected to, another. Their color and density vary according to the period of their formation, the older being usually of a pale, yellowish appearance, and of a firm, fibrous consistence, while those that are of a comparatively recent date exhibit very much the aspect and consistence of a common heart clot. Their thickness ranges from the fourth of a line to that of a sheet of paper, their number being often immense, thousands existing in a tumor, perhaps, not larger than an ordinary fist. That these concretions are organized, at least in many cases, is evinced by their intimate adhesion, not only to each other, but also to the inner surface of the sac, by their extraordinary density, and by their yellowish hue, which contrasts most strikingly with that of recently deposited fibrin and coagulated blood. These circumstances show that these lamellæ undergo most important changes after they have been deposited; that absorbent vessels are busily engaged in carrying away the serum and coloring matter of the blood, and in solidifying the fibrin after it has been extricated from the general mass; while the successive development of concretions clearly denotes that the process is as much a vital as a mechanical one. No arteries and veins have, I believe, yet been demonstrated in them; but that such vessels are always present—often, indeed, in great numbers—in cases of long standing, does not admit of any reasonable doubt. We may, therefore, look upon these clots as exceedingly interesting structures, capable, after a certain period, of maintaining a kind of independent existence. Their primary object evidently is to strengthen the aneurismal sac, and, under favorable circumstances, to fill it up, so as to effect a radical cure. What adds to the force of this conclusion is the fact that, when a cure of this description has been effected, the tumor is gradually brought under the influence of the absorbent vessels, by which it ultimately entirely disappears, with the exception, perhaps, of a little nodule not larger than a pea, and just sufficient to indicate the former site of the disease. It is proper to state that the recently-formed strata of an aneurismal sac are, in general, very imperfectly, if at all, organized; they are certainly not vascularized and furnished with absorbents.

How are these aneurismal concretions formed? Upon this subject there still exists some contrariety of sentiment. Most pathologists, however, suppose, and very correctly, as I think, that they are deposited from the blood as it sweeps over the inner surface of the sac, during which more or less of its fibrin is disengaged, while the other elements of the fluid are sent forward to mingle with the current in the affected artery. This opinion derives plausibility from the fact that the development of these strata always proceeds most rapidly when there is a comparatively small orifice of communication, with a languid state of the systemic and of the aneurismal circulation. It has been conjectured that the clots had their origin in an effusion of plastic matter, such as occurs in injuries and ordinary inflammation; but for such a view I can myself perceive no just ground, as it is impossible to discover the slightest similarity between the two processes. The act of formation, as stated in the preceding paragraph, is both a mechanical and a vital one; mechanical, as far as the mere separation of the fibrin from the blood is concerned; vital, as it respects the decolorization, condensation, and intimate adhesion of the concretions.

The *tubular aneurism* is extremely rare; it is observed principally in the aorta and

its larger branches, especially the innominate, carotid, and iliac, and consists in a uniform dilatation of the vessel, usually composed of all its tunics in varying degrees of alteration. In its shape, the tumor is commonly somewhat spindle-like, and hence it is often described under the name of fusiform aneurism ; the term cylindroid has also been applied to it, as its conformation occasionally partakes strongly of that character. The word tubular, however, is more expressive of its appearance, and I therefore adopt it in preference to any other. The annexed drawing, fig 321, from a specimen in my collection, affords a good idea of this variety of the disease.

The size of the tubular aneurism varies from slight increase of the normal diameter of the vessel to a tumor capable of receiving a large fist. When it occupies the arch of the aorta, it often projects up into the neck so as to form a prominent swelling above the sternum, admitting of satisfactory examination, both by touch and auscultation. The distance between the roots of the carotid arteries is greatly increased, and the aneurism generally encroaches sensibly upon the heart. In nearly every instance its length considerably exceeds its diameter. The dilatation of which it consists seldom terminates abruptly, but is lost by insensible degrees in the vessel above and below, thus giving the tumor the appearance of two cones united at their

Fig. 321.

Tubular Aneurism of the Aorta.

bases. In the smaller arteries, as, for example, the innominate, the aneurism sometimes involves the whole length of the vessel.

The structure of the tubular aneurism is usually made up of all the tunics of the affected artery, in a notable state of alteration, of which hypertrophy constitutes the most striking feature. In two remarkable specimens in my collection, the different tunics are immensely thickened, and increased in strength and density, the effect, evidently, of long-continued interstitial deposits ; they both occupied the arch of the aorta, extending as far as the root of that vessel, and were taken from male subjects upwards of fifty years of age. The lining membrane has lost its white and glossy appearance, and has been replaced by a thick, opaque, and rugose structure, having none of the properties of the original texture. The middle coat is at least ten times as thick as natural, very strong, elastic, and deprived of its yellowish hue ; the outer one is also greatly changed in its appearance, being remarkably strong, thick, and firm. No evidence whatever exists in any of the tunics of the earthy, atheromatous or fatty degeneration.

From a careful examination of this form of aneurism, it appears to me to consist essentially in a dilatation of the caliber of the artery, with hypertrophy of its different tunics. The first step, probably, in its formation is chronic inflammation, causing weakness of the walls of the vessel, and uniform enlargement of its diameter. By and by, however, as the dilatation increases, the coats become strengthened in every direction by interstitial deposits, and it is thus that a tumor is at length formed, capable of offering great resistance to the impulse of the blood. It is owing to this superaddition of matter that the tubular aneurism so seldom gives way by rupture ; a circumstance in which, as well as in several others, it differs remarkably from the sacciform variety of the disease.

It is not to be supposed, from what precedes, that this form of aneurism always consists of the different tunics of the affected artery ; this is unquestionably true in most cases, but we now and then meet with an instance in which the lining membrane, and perhaps, also, the middle layer, are partially deficient, thus causing irregularity in the dilatation, unless, as occasionally happens, the defect is atoned for by plastic deposits. Indeed, the retention of all the tunics would seem to be an essential condition to the formation of the true tubular aneurism ; if the inner and middle lamellæ be destroyed, even to a small extent, the blood will dilate the vessel unequally, and inevitably give rise

to a sacculated tumor. It is in this way that may be explained the occasional coexistence of the two forms of the malady.

The tubular aneurism is remarkable, besides some of the characters already pointed out, for the absence of fibrinous concretions, which are so common in the sacciform; and the circumstance may be employed as an additional evidence of the correctness of the view, so long and so generally entertained, that the formation of these substances takes place directly from the circulating fluid, and not, as some have conjectured, as an effect of the deposition of plastic matter, consequent upon inflammation. If the development arose in the latter way, it ought to be of frequent, if not of constant occurrence, inasmuch as the inner coat of the affected artery is seldom entirely free from inflammation, and would thus afford a large surface for the effusion of fibrin; but every one who has ever examined a specimen of tubular aneurism knows how extremely rare it is to find its walls incrusted with anything. In the annexed sketch, fig. 322, from Hodgson, a tubular aneurism is seen to be occupied by concretions, with a central canal, which preserves the continuity of the vessel, and thus maintained the circulation. The stratification appears to have been very perfect.

Fig. 322.

Aneurism by Dilatation. The Abnormal Space is almost entirely filled up by Fibrin; the Arterial Canal remaining clear. Spontaneous Cure exists in an advanced stage.

A *diffused* aneurism, as it is termed, is, strictly speaking, an outgrowth of the circumscribed variety, especially of the sacciform, which, during the progress of its development, is liable to give way by the partial destruction of its sac, followed by an escape of blood. The immediate cause of such an occurrence is ulceration, gangrene, or rupture, the effect of muscular exertion, violent cardiac impulse, or severe compression. It is thus that an aneurism, originally quite small, and distinctly circumscribed, may eventually become diffused and of enormous dimensions, the blood being more or less extensively infiltrated into the surrounding tissues, separating them from each other, and thus adding greatly to the patient's suffering, as well as to his peril. This secondary occurrence usually takes place late in the advanced stage of the disease, from gradual weakening of the sac by the pressure of its contents, or by the pressure of the parts around, leading either to rupture or ulceration. Only a small quantity of blood may escape in the first instance, and, if it should coagulate very firmly, the clot so formed may, for a time, serve as an effectual barrier against further loss. Most generally, however, the effusion is great and rapid, and local suffering proportionately imminent. The newly extravasated blood is sometimes intermixed with fibrinous concretions, especially such as are of more recent formation and have not yet become firmly adherent to each other and to the sides of the sac. However this may be, it usually speedily coagulates, gradually increases in consistence, and ultimately, perhaps, even undergoes a certain degree of organization, more particularly if the patient survives the accident for any considerable length of time. Meanwhile, the structures among which the blood has been extravasated become more or less indurated, inflamed, and infiltrated with serum, while the abnormal pouch itself is incrusted with plastic matter; an arrangement evidently designed to protect the sac, and to prevent it from breaking at once through its confines. Eventually, however, if life be not worn out by pain and irritation, the tumor is sure to give way by ulceration, gangrene, or rupture, followed more or less speedily by death.

3. SYMPTOMS OF ANEURISM.

The symptoms of aneurism exhibit, as might be supposed, much diversity, the principal circumstances which influence them being the nature, seat, and age of the tumor. Hence, in order to comprehend the subject thoroughly, it must be studied with special reference to these points.

In spontaneous aneurism, usually dependent upon rupture of the coats of an artery, the patient is often apprised of the commencement of the disease by the occurrence of a sharp pain, not unlike that produced by an electrical shock; he feels as if he had received a smart blow, and, perhaps, turns to see who inflicted it. Occasionally, also, he is conscious of something having suddenly given way—he may even have heard a slight noise —and on examining the part, a small, pulsating tumor is found. Upon being interrogated as to the cause of the accident, he will usually state that it took place while he was engaged in some severe bodily exertion, as leaping, running, lifting, or coughing. But the origin of the disease is not generally thus marked; in the majority of cases, in fact, the patient has no distinct perception of its occurrence, and he is only apprised of its existence by degrees; not, perhaps, until it has already made serious progress. Such an event will be particularly apt to happen when the lesion consists essentially in a dilated condition of the arterial tunics, unattended with rupture, as it is then often extremely stealthy in its mode of invasion. In traumatic aneurism, on the contrary, the characteristic symptoms ordinarily show themselves immediately after the receipt of the injury of the vessel upon which the disease is situated.

The aneurismal tumor is usually quite small at its commencement, not exceeding, perhaps, the volume of a filbert, a small hickory-nut, or an almond; by degrees, however, it augments in size, and may ultimately acquire a bulk equal to that of a man's fist, or even of an adult's head. In its form it may be globular, elongated, ovoidal, conical, fusiform, or cylindrical; or so irregular as to defy description. However this may be, it is a living, beating tumor, rising and expanding synchronously with the contraction of the left ventricle of the heart. Its pulsations are often perceptible at the distance of a number of feet, especially in strong, plethoric subjects, and are always increased in force and frequency by whatever has a tendency to excite the general circulation. It imparts a distinct impulse to the hand, rising and falling as the blood enters and passes out; it is soft and elastic, and in its earlier stages permits itself to be emptied by steady and uniform pressure. Upon applying the ear to the tumor, a peculiar noise is perceived, differing very much in its character and intensity. In general, it is a kind of sawing, rasping, hissing, or bellows sound, so loud as to be heard with great distinctness at a distance of several inches; occasionally it is of a peculiar whizzing, whirring, or purring nature, and cases occur, although they are rare, in which it strongly resembles the buzzing of a fly in a bottle. The immediate cause of the sound is the manner in which the blood rushes into the tumor; its pitch is always greatest, other things being equal, when there is a comparatively small opening of communication, and when the sac, containing but little solid matter, is seated superficially.

The phenomena now described are generally susceptible of great modification by pressure applied to the artery above and below the tumor. In the former case, the size of the swelling is notably diminished, and all motion and noise disappear; in the latter, it is sensibly augmented, the tumor heaves and rises under the resistance, and the blood, rushing violently against the inner surface of the sac, at each systole of the heart, produces great tumult, with a corresponding increase in the intensity of the different sounds. Considerable changes in the aneurismal sounds are sometimes occasioned by the rugose condition of the margins of the orifice of communication, and by partially detached clots, or projecting filaments, within the sac, intercepting the column of blood, and causing various murmurs and vibrations, together with a tremulous shaking of the tumour, isochronous with its pulsations.

The pain attendant upon aneurism is constant, but subject to variation in its intensity; slight early in the disease, and while the swelling is still small; more severe and harassing as it progresses and encroaches upon the surrounding parts. Diversified in its character, it is generally dull, aching, and throbbing, as if matter were about to form; in some cases it is sharp and darting, in others dull, heavy, or gnawing. Occasionally it is of a neuralgic nature, coming in fits and starts, or, as sometimes happens, in regular paroxysms, once or twice in the twenty-four hours. The immediate causes of the pain are, inflammation of the sac, and the pressure of the sac upon the neighboring structures; hence, as a general rule, it is always most violent in large and old aneurisms, and in those parts of the body which are most abundantly supplied with nerves, or where there is naturally a great deal of dense, firm, unyielding structure, interfering with the development of the tumor.

For the same reason that the pressure of the tumor causes pain, the distal parts usually suffer from numbness, and a sense of aching and weariness. Their temperature is diminished, and they are weak and crippled. Great swelling, of an œdematous character, is

often present, the result, evidently, of the compression of the veins and lymphatics impeding the return of their contents. As the tumor enlarges, the distal portion of the artery contracts, and conveys less of its wonted supply to the part below it. Gradually, however, this is compensated for by the collateral vessels, which, naturally existing, augment in size, and, in time, amply atone for the diminished stream in the main trunk. If it were not for this arrangement, the parts would soon shrivel and wither, or, worse, fall a prey to gangrene. Fortunately, such an event can only happen when the aneurism is of extraordinary bulk, or of very rapid development, thereby compressing also the collateral vessels and the principal nerves.

Aneurism of the thoracic aorta, and of the innominate and carotid arteries, is nearly always attended with distressing dyspnœa, severe pain, and palpitation of the heart, which is itself often seriously implicated in the disease, being especially liable to suffer from hypertrophy, softening, and fatty degeneration, along with chronic endocarditis and disorder of the tricuspid and semilunar valves. As the tumor enlarges, the respiratory difficulty rapidly increases, rendering walking painful, and the maintenance of the recumbent posture ultimately impossible. Compression of the trachea may induce asphyxia; of the œsophagus, inanition. In the abdomen and pelvis, aneurism of the larger arteries, besides causing violent pain, may occasion serious functional disturbance, by interfering with the return of the blood in the vena cava, and thus leading to ascites and anasarca.

4. DIAGNOSIS OF ANEURISM.

Although the symptoms of aneurism are, in general, so well marked as to render it difficult to mistake their import, yet, as the disease may be simulated by other affections, and as doubts may thus arise in the mind of the inquirer concerning its true nature, it is necessary, in every case, however well characterized it may apparently be, before he comes to a final decision, to institute a faithful examination into its history, progress, and existing condition. It has been for the want of proper care in the investigation of this disease that some of the most serious and disgraceful blunders that disfigure the records of surgery have been committed; and, although such errors are now less frequent than they were formerly, owing to the more general use of the exploring needle, and a better acquaintance with pathological anatomy, yet it cannot be denied that what has occurred once may happen again, and that with tenfold effect, as it respects the character of the surgeon, who, to his skill as an operator, is always supposed to unite that of an enlightened diagnostician. The affections with which aneurism is most liable to be confounded are, chronic abscesses and different kinds of tumors, especially the glandular and encephaloid sarcoma. Attention to the following circumstances cannot fail, if carefully considered, to protect the practitioner from error.

1. Aneurism is always, from the first, seated in the direction of one of the larger arteries, whose course may often be distinctly traced by the finger; it is soft and elastic, pulsates more or less violently, is free from pain, and is unattended with discoloration of the integument. Abscess, on the contrary, begins as a hard swelling, and becomes soft only after it has passed through its different stages; if chronic, matter will form very slowly, and, although it may surround the artery, and thus receive its impulse, yet the peculiar fluctuation of the swelling, and the changes that may be induced in it by pressure and posture, will always suffice to prevent error. In acute abscess, there is severe pain, pus is poured out rapidly, and there is marked discoloration of the surface, with more or less constitutional disturbance. Glandular lymphatic swellings are most common in the neck, axilla, and groin in children and young persons of a strumous diathesis; they generally advance pretty rapidly, and, after having attained a certain bulk, either remain stationary, or alternately advance and recede; they are usually multiple, and not unfrequently occur simultaneously on both sides of the body. External aneurism, on the contrary, is most common in the popliteal, femoral, innominate, and carotid arteries in middle-aged and elderly subjects, and, progressing slowly but steadily, never recedes, and rarely exists in more than one situation at the same time. Sarcomatous growths occur at all periods of life and in nearly all regions of the body; soon acquire a large bulk; are of varying degrees of consistence, some parts being solid, some soft, and some semisolid; are attended with great enlargement of the subcutaneous veins; and soon give rise to a pale and sallow state of the features. Aneurism, as just stated, advances tardily, is of uniform consistence, especially in its earlier stages, is not accompanied by any enlargement of the subcutaneous veins, and, although the general health may seriously suffer, there is an entire absence of carcinomatous impress.

2. Aneurism pulsates the moment it is developed; no matter how small it may be, it throbs and heaves isochronously with the heart, and possesses all the characteristic traits that distinguish it in its later stages, although they are, perhaps, less strongly marked. Abscesses and solid tumors, on the contrary, are seldom affected by the beating of the underlying vessel until they have acquired some bulk, and even then the impulse is often very faint, occurring rather as an undulatory movement than as a distinct shock.

3. In aneurism the tumor is generally firmly fixed, any attempt to grasp and lift it up proving abortive; possibly, it may be pushed gently to one side or the other, but this is all. Moreover, whatever changes may be effected in its relations, none can be effected in its pulsations; it throbs and heaves as before. With solid growths this is not so; unless very large, they can readily be isolated from the vessel, and be thus deprived of all impulse, however strong.

4. The pulsation in aneurism is generally uniform, being perceived equally at every point of the circumference of the tumor, which rises and falls synchronously with the systole and diastole of the heart; in abscesses and solid growths, on the other hand, it is very irregular, and is usually limited to some particular spot. In aneurism the swelling bounds and recedes under the hand; it feels as if it were alive and panting; in solid tumors the morbid mass rises at each impulse, but there are no expansion and contraction.

5. When an aneurism is firmly and uniformly compressed, it sensibly diminishes in bulk, which, however, recovers itself the moment the hand is removed; in solid growths and abscesses, pressure produces no such effect.

6. In aneurism, the size of the swelling is diminished by pressure upon the cardiac side of the tumor, and increased by pressure upon the distal side. In morbid structures not arterial, no change of bulk follows this procedure.

7. The sounds of aneurism are different from those of solid tumors. Both may yield a sawing, bellows, or rasping noise, but in the latter this is never conjoined with the peculiar thrill, or whirring noise, which constitutes so prominent a symptom in the former.

8. Aneurism of the larger arteries ordinarily affords two alternate shocks, one of which corresponds with the diastole of the heart, the other with its systole. These phenomena are never present in solid tumors and abscesses, and are therefore pathognomonic.

When, as is sometimes, though very rarely, the case, an aneurism opens into an abscess, the ordinary phenomena, as pulsation, bruit, and thrill, are suddenly superadded to those of the latter disease, with great increase in the volume of the tumor, and more or less marked expansion of its walls. Such an occurrence is most common in the neck, axilla, groin, and ham, in consequence of chronic suppuration, and demands special vigilance for its successful discrimination.

An aneurism has occasionally been mistaken for rheumatism, and, conversely, rheumatism for aneurism. I have known the pain and swelling caused by an aneurism of the popliteal artery to be treated for rheumatism of the knee-joint; and a number of instances have fallen under my observation in which the pulsation and expansion that are so liable to accompany neuralgia of the abdominal aorta and of the innominate and carotid arteries were supposed to have been occasioned by aneurism of those vessels. Finally, aneurism may be simulated by anemia, especially when it occurs in conjunction with neuralgia, or neuralgia and rheumatism, in a person of broken-down constitution. Errors of diagnosis, under such circumstances, are generally easily avoided by a thorough examination of the part affected, and by a careful consideration of the history of the case.

Such are the distinguishing characters of aneurism and of the more important diseases with which it is liable to be confounded. It must be obvious, from what has been said respecting them, that mistakes can only be avoided by the most rigid and thorough examination, made not once, but repeatedly, in every case of tumor situated along the course of an artery and influenced by its pulsation. When, after such a painstaking process, no satisfactory decision can be arrived at, the only resource is the insertion of a delicate exploring needle, which, while it can do no possible harm, if it be properly employed, will at once determine the diagnosis.

Serious, and sometimes even fatal, accidents occur during the examination of an aneurismal tumor, either from a detachment of some of its clots, causing embolism, or from a rupture of the sac, followed by destructive hemorrhage. In a case of aneurism of the common carotid artery, the size of a hen's egg, reported by Esmarch, firm pressure upon the tumor suddenly produced symptoms of apoplexy, of which the patient died in three days; and in a similar case, recorded by Mr. T. P. Teale, of Leeds, hemiplegia was suddenly induced, ending in death in a few weeks. In both of these instances the trouble

was no doubt occasioned by obstruction of some of the cerebral arteries, by small clots finding their way into the brain. Dr. Bontecou, of Troy, several years ago, tied the external iliac artery in a case of inguinal aneurism, ruptured by the manipulations of a professional rubber, employed to relieve pain. The rude handling of an aneurism sometimes gives rise to violent inflammation of its sac, followed by gangrene and death. Facts like these should teach the surgeon the importance of great caution in his attempts at arriving at a correct diagnosis in tumors situated in or involving arteries, especially those of the neck, ham, and the abdomen.

5. EFFECTS AND TERMINATION.

The effects which an aneurism exerts upon the surrounding parts vary according to circumstances, of which the most important are, the situation of the affected vessel, and the size of the tumor. An aneurism of the arch of the aorta produces, other things being equal, more serious disturbance, both organic and functional, than one of the abdominal portion of that vessel, and an aneurism of the carotid artery than one of the popliteal. It is obvious also that a small tumor will, as a general rule, cause less serious effects than a large one.

The effects which such a disease produces upon the parts with which it is in contact are purely of a mechanical character, eventuating in their displacement, compression, or ulceration, or in all these occurrences combined. An aneurism of the thoracic portion of the aorta must necessarily encroach more or less upon the contents of the chest, pushing the heart and lungs out of their natural position, and thereby interfering essentially with the performance of their proper functions. In aneurism of the carotid artery there will be displacement of the trachea, œsophagus, and the great vessels of the neck, along with compression of these parts, and also of the pneumogastric and sympathetic nerves. In popliteal aneurism the portion of the limb below the site of the tumor generally suffers from obstructed circulation, as is evinced by the occurrence of anasarca and decrease of temperature, with a feeling of numbness, the result of interruption of the nervous current. When the embarrassment to the flow of blood is very great, or long continued, mortification of the distal portion of the limb is liable to ensue.

When the tumor is situated externally, it may produce serious changes in the muscles, which, in many cases, are not only widely separated from each other, but remarkably pale, flattened, and attenuated, exhibiting more the appearance of thin ribbons than of thick, solid, fleshy bodies. The nerves, too, are often very much spread out, the vessels are thrust aside, and the aponeuroses are stretched out like tense sheets. When pressing upon an important joint, the tumor is sure to impede its motion, and may even cause permanent ankylosis, as occasionally happens in aneurism of the popliteal artery.

The effect produced by aneurism upon the osseous tissue is sometimes very remarkable. It is generally most conspicuous in the dorsal portion of the spine. When the disease involves the thoracic aorta, the tumor, crowded into a comparatively small space, is liable, especially when it is of large bulk, to encroach seriously upon the bony walls of the chest, pressing upon and eroding the bodies of the vertebræ behind, as seen in fig. 323, the sternum in front, the ribs at the side, and the clavicle above. There is no osteological cabinet, of any extent, that does not contain specimens of this kind. I have seen cases where as many as four of the bodies of the dorsal vertebræ were completely absorbed as far as the spinal canal, which, forming the posterior boundary of the tumor, was thus freely exposed to its pulsations. The sternum suffers mostly at its lateral and upper aspect, but occasionally, as in an instance now under my care, it is perforated at the centre, the movements of the aneurism being distinctly visible at that part. The ribs and their cartilages do not generally participate to any considerable extent in the erosion, and the clavicles are rarely affected, unless the tumor is of great bulk, and projects unusually high up into the neck.

Fig. 323.
Erosion of the Vertebræ from Aneurism.

It is not surprising, after what has been said respecting the effects which aneurism is

capable of exerting upon the osseous tissue, that the tumor should occasionally cause serious lesion in the soft structures, apart from their mere compression. In its earlier stages, before the swelling has attained any considerable bulk, the inroads are slight, and, consequently, well borne, the parts manifesting no disposition to resent its encroachments; by and by, however, as it progresses, its pressure bears heavily upon the adjacent textures, which, taking on inflammatory action, become matted together by interstitial deposits, which, for a time, thus materially strengthen the aneurismal sac. But such a state of things is not destined to last long; gradually the morbid action increases, the superincumbent tissues are more and more expanded, and, at length, ulceration setting in, the integument yields over the more prominent portion of the sac, followed by destructive hemorrhage.

6. SPONTANEOUS CURE.

Unfavorable as the prognosis of aneurism generally is, it is gratifying to know that a cure is occasionally effected spontaneously, without the intervention of art in any way. That such an event is rare, forming merely an exception to the great law, is unfortunately too true; yet it sometimes occurs under circumstances, apparently, the most desperate, bidding defiance alike to medical and surgical skill. There are, indeed, few practitioners of enlarged experience who have not met with cases of this disease in which, contrary to all calculations of the doctrine of chance, the patient made an excellent recovery, after having literally hovered, for days and weeks, over the very verge of the grave; where, in short, everything portended speedy destruction, and yet every vestige of the aneurism ultimately disappeared, the person living for years afterwards in the enjoyment of good health, and in the exercise of his former occupation. How the cure is effected in these cases our information does not enable us to explain, as an opportunity is seldom afforded of making a dissection of the body after the event has taken place, in consequence of the individual being usually lost sight of. A knowledge, however, of the possibility of such a cure is highly encouraging, and holds out the hope that it may be of more frequent occurrence than has hitherto been imagined.

The most remarkable case of the spontaneous cure of this disease that I have ever seen, was that of a gentleman sixty-two years of age, whom I attended in January, 1862, along with Dr. E. L. Carter. The tumor, which had come on about twelve months previously without any assignable cause, presented all the characteristic features of an aneurism of the left subclavian artery. It occupied the whole of the triangular space above the clavicle, between the trapezius and sterno-cleido-mastoid muscles, where it formed a large prominence, heaving and pulsating synchronously with the contraction of the left ventricle of the heart, and imparting a peculiar blowing or sawing sound to the ear. The patient experienced excessive pain in the tumor, as well as in the shoulder and arm; there was great numbness of the whole extremity, and he was obliged to be constantly propped up in bed, as well as to use anodynes freely to enable him to sleep. The prognosis, in fact, could not have been more unpromising. Early in May, however, he was able to take gentle exercise in the open air; his health now gradually improved, and the tumor began to diminish in size, the process of absorption steadily progressing until December, 1863, when every trace of it had disappeared. The left arm and hand remained cold and atrophied, but in all other respects the recovery was perfect. The treatment consisted principally of the internal use of iron and quinine, along with a properly regulated nutritious diet.

Although we are not always able to account for the manner in which the patient recovers in this disease, observation has demonstrated that it generally occurs in one of five ways, all leading, essentially, to the same result, namely, the formation of clots, by which not only the aneurismal sac is closed up, but also the artery immediately above and below it. When the cure is gradual, the clots are usually arranged concentrically, and exhibit every mark of organization; but the reverse is the case when it is effected suddenly, for then they are nothing but soft, red blood-masses, similar to what are so often observable after death in the heart and large vessels.

1. The most common way in which the cure takes place is by the gradual filling up of the sac by the formation of clots, thereby ultimately converting it into a firm, solid tumor. The most beautiful and perfect specimen of this kind, sketched in fig. 324, that I have ever seen, was presented to me by an old pupil, Dr. Shumard, who had removed it from the body of a young steer. What renders it still more interesting is the circumstance that it was connected with the hepatic artery, which had given way at one side from the rupture, apparently, of its inner and middle tunics. The tumor, which is of a

rounded shape, and nearly three inches in diameter, is occupied by hundreds of lamellæ, many of them not thicker than a sheet of paper, of a pale grayish color, closely adherent to each other, concentrically arranged, of a dense, firm texture, and, beyond question, thoroughly organized, even those most recently deposited. At the centre of the tumor, a large irregular cavity exists, which still admitted some blood, as is proved by the fact that the hepatic artery is completely pervious. Such a mode of repair is greatly facilitated by the small size of the opening of communication between the artery and the aneurismal sac.

Fig. 324.

An Aneurismal Tumor obliterated by the Deposition and Organization of Fibrin.

2. Another mode of spontaneous cure is the occurrence of inflammation, followed by the coagulation of the contents of the sac, and the ultimate obliteration of its cavity as well as of the artery in its immediate vicinity. The disease may begin in the tumor itself, or be propagated to it from the circumjacent structures; if it is mild and slow, the cure may be easy and safe, but if very active, it may terminate in suppuration, and thus endanger life by hemorrhage, the matter being evacuated along with the clots before the artery is hermetically sealed by an internal coagulum.

3. The repair occasionally occurs through gangrene, either beginning in the tumor itself, or extending to it from the parts immediately around it. The blood coagulates in the sac as in an artery in ordinary gangrene, and when the sloughs separate the clots are discharged, the gap being afterwards closed by the granulating process. Such a mode of restoration must necessarily be infrequent, inasmuch as the morbid action by which it is effected generally terminates fatally.

4. The contents of an aneurism are sometimes solidified by the compression of the artery leading to it, caused either by the tumor itself or by some morbid growth in its immediate vicinity. Such a result may follow with nearly equal certainty, whether the pressure is applied to the cardiac or to the distal portion of the vessel.

5. Finally, there is a very rare mode of spontaneous obliteration, consisting in the detachment of a small clot and of its introduction into the distal portion of the artery, thereby more or less completely blocking it up. The blood, thus checked in its onward flow soon coagulates, just as in artificial compression. It was upon a knowledge of this species of spontaneous cure that the late Sir William Fergusson, many years ago, attempted to found a new mode of treatment of aneurism by breaking up the contents of the tumor by manipulation, and urging on some of the fragments into the distal communicating vessel.

When, by any of the above modes, a radical cure is effected, the tumor is gradually brought under the influence of the absorbent vessels, and is ultimately completely obliterated; or, at all events, so far reduced as to leave only a small nodule, indicative of the former site of the disease. The period required for the perfection of these changes varies from three or four weeks to as many months, according to the size of the aneurism and the state of the part and system.

Although an aneurism may occasionally get well spontaneously, or under internal treatment, such an event is entirely exceptional. The great law of the disease is death. The period at, and the mode in, which this takes place are extremely variable, and can, therefore, be pointed out only in a general manner. In aneurism of the aorta, especially in the arch of this vessel, the disease often terminates in less than three months from its commencement; in the innominate its course is generally also rather rapid, and a similar remark applies to aneurism of the primitive iliac; in aneurism, on the contrary, of the carotid, subclavian, axillary, external iliac, femoral, and popliteal arteries, the fatal event is often postponed several months longer. To these statements they are, of course, many exceptions; thus, on the one hand, we occasionally meet with an aneurism that kills in a few weeks, the tumor expanding rapidly, and, perhaps, bursting quite suddenly during a violent muscular effort; and, on the other, the disease may continue, with very little variation, as to size, for a number of years.

There are three distinct modes in which aneurism may cause death: 1. By the injuri-

ous compression which the tumor exerts upon the neighboring organs.   2. By the sudden rupture of the sac, and the occurrence of hemorrhage.   3. By the development of inflammation, suppuration, or mortification.

1. Aneurismal tumors of the neck and chest often cause death by compression of the trachea and bronchial tubes, although perhaps not so frequently as has generally been supposed, owing to the wonderful power which these tubes possess of flattening themselves so as to make room for the entrance of air into the lungs.   Indeed, I am inclined to think that death from direct suffocation, from this cause, is an uncommon event.   Great difficulty is often produced by the pressure of the sac upon the pneumogastric and phrenic nerves, and it is extremely probable that life is sometimes destroyed in this way, the more especially when the pressure is conjoined with serious lesion of the air-passages.   Finally, death occasionally proceeds from compression of the heart and lungs, interfering with the circulation and respiration; or from compression of the œsophagus, causing inanition.   In the abdominal and pelvic cavities, and also in the extremities, the danger from compression is not nearly so great, as the structures here are less important to life, as well as more disposed to yield under the encroachment of the tumor.

2. After an aneurismal tumor has attained a certain bulk, it is extremely apt to give way, as in fig. 325, either suddenly or gradually, under the impulse of the blood, or under severe muscular exertion.   Such an occurrence will be

Fig. 325.

the more likely to happen when the tumor has been of rapid growth, and especially if its interior has not been fortified by the formation of hard, organized clots, so as to increase the thickness and strength of its tunics.   It is in this manner that most of the internal aneurisms, which do not cause destruction by mere compression, ultimately terminate, the immediate cause of death being hemorrhage into some internal and contiguous organ.   Thus, in the chest the tumor usually opens into the trachea, bronchial tubes, pleura, pericardium, mediastinum, or œsophagus.   Sometimes a communication is established between the sac and the heart, between it and the pulmonary artery, or lastly, between it and the vena cava.   An aortic aneurism has also been known to burst into the spinal canal, some of the bodies of the vertebræ having previously been destroyed by absorption. In the abdomen, the tumor may break into the peritoneal cavity, or into one of the hollow viscera, as the stomach, intestine, or urinary bladder.   In the neck, axilla, groin, and extremities, an aneurism, if permitted to pursue its course, generally finds its way to the surface, very much after the manner of an abscess.

The hemorrhage succeeding to the rupture of an aneurism may be slight, as when the aperture is small or devious, or copious and destructive, as when the opening is large or straight. Most commonly, life is worn out by the frequent recurrence of the bleeding; thus, twenty ounces of blood may be lost to day, in a week twenty or thirty ounces more, and so on until the

Aneurism of the descending Aorta, burst, the Patient dying suddenly in consequence.

patient dies completely exhausted, his condition being, in the mean time, perhaps sadly aggravated by serous effusions into some important cavity.   Occasionally the aneurism gives way by a large rent, and the patient expires instantly from hemorrhage.   On the other hand, the sac may give way, and yet there may be no hemorrhage, the patient finally perishing from some other cause.   Thus, in the case of Mr. Liston, the opening which had formed between the aneurism and the trachea was clogged up with a mass of coagulum, which effectually prevented the escape of blood, death finally resulting from the irritation produced by the pressure of the tumor upon the inferior laryngeal nerve.

3. More or less inflammation attends all aneurisms; whatever may be their volume, situation, age, or character, they play the part of intruders, encroaching upon, compressing, and irritating the surrounding structures, and thus giving rise to various deposits, especially of serum and plasma.   It is by means of the latter that, as was previously stated, the sac increases in thickness and density, so as to qualify it the better to bear with impunity the impulse of the inflowing current of blood; without such an occurrence few tumors of this kind would be able to maintain themselves for any length of time, but would soon yield to the resistless pressure from within; in a word, speedy rupture of

the sac, and fatal hemorrhage, would, in most cases, be inevitable. But, although inflammation is set up for wise and beneficial purposes, the process, unfortunately, is not always kept within the strict limits required to fortify the sac and protect it against early rupture; on the contrary, many circumstances concur to provoke its increase, and to cause it to pass into ulceration, suppuration, or even mortification. Among these circumstances some are of a constitutional, others of a purely local, character; thus, mere plethora and the use of stimulating food and drink may powerfully augment the inflammation, and bring about these untoward results. In general, however, it will be found that the mechanical compression of the tumor, in consequence of the resistance offered to its extension, has more to do with its production than anything else. Sometimes a clot is accidentally detached, and thus becomes a cause of mischief. In external aneurism, the manipulation employed in examining the tumor is occasionally productive of severe inflammation, and similar effects often follow the injudicious use of the affected limb.

Suppuration of the tumor is an infrequent event. A case occurred in 1857, at the Pennsylvania Hospital, in the service of Dr. Pepper, in which an abscess had formed in connection with an aneurism of the innominate artery, and destroyed the patient, a man aged thirty-eight, by bursting into the trachea. A report, with a drawing of the case, has been published by Dr. Humphreys, in the Transactions of the Pathological Society of Philadelphia. Ulceration and mortification are more common, and are particularly liable to take place when the tumor is of large size.

Finally, aneurism may prove fatal by exciting inflammation in an important internal organ, as the lung, heart, or pleura. In popliteal aneurism, the pressure of the tumor upon the nerves and arteries below sometimes causes death from mortification of the leg and foot.

TREATMENT.

In the time of Celsus, as well as for a long period subsequently, the treatment of external aneurism was conducted in the most cruel and unscientific manner. The only operation which appears to have been known was that of laying open the tumor by a bold incision, and, after turning out its contents, applying the hot iron to the extremities of the affected artery, so as to seal up their mouths. The effect of such a procedure may easily be imagined; upon the separation of the eschar, hemorrhage was sure to take place, and in this way nearly every patient perished, either at the first onset of the bleeding, or by its frequent repetition. This miserable practice continued in vogue until the time of Antyllus, in the third century, who adopted a more scientific, although hardly a less hazardous, procedure. It consisted in freely opening the tumor, clearing out its contents, and tying the artery above and below, the ends of the vessel having previously been searched for with a probe. The sac was then stuffed with charpie, to promote suppuration and occlusion, the object being to heal the wound from the bottom. Occasionally the more adventurous surgeon took the more speedy route of extirpating the tumor, adopting a plan similar to that which is sometimes pursued at the present day in treating aneurism at the bend of the arm consequent upon venesection and other injuries. The result, too, of this operation was often most disastrous; many of the patients died of the effects of inflammation, some of secondary hemorrhage, and not a few of the shock of the amputation performed, as a dernier resort, to save them from impending destruction. To prevent these sad occurrences, and afford the sufferer a better chance of recovery, the removal of the limb was often the only expedient thought of for his relief.

The operation of Antyllus has been repeatedly performed for traumatic aneurism at the bend of the arm. Morel, of Paris, performed it in a case of carotid aneurism in the seventeenth century; Keyslére, in 1744, performed it in a case of popliteal aneurism, and Sabatier, not long afterwards, in a case of femoral aneurism. Mr. Syme, of Edinburgh, employed it successfully in aneurism of the common carotid, axillary, and internal iliac arteries, his first case having occurred in 1857. Several other surgeons have been equally daring.

a. DELIGATION OF THE ARTERY AT THE CARDIAC SIDE OF THE TUMOR.

It is very surprising that some of the procedures above described should have continued in vogue until near the close of the last century. The fact attests, more fully than any other circumstance with which we are acquainted, the low state of surgery up to that period. The merit of performing the first operation for the cure of aneurism upon strictly scientific principles is due to John Hunter. From having witnessed so

many failures from the ordinary methods, he was led to the conclusion that the cause consisted in the fact that the artery is always diseased for some distance above the aneurism, and that it was, therefore, incapable of becoming sufficiently occluded prior to the detachment of the ligature to prevent hemorrhage. Acting under this conviction, amply confirmed by dissection and observation, he determined, upon the first favorable opportunity, to apply the ligature to a sound portion of the vessel. While thus revolving the matter in his mind, a man, laboring under popliteal aneurism, was admitted into St. George's Hospital, of which he was then one of the surgeons. The patient was a coachman, forty-five years of age; and the tumor, first perceived three years previously, was not only quite large, but attended with great swelling of the foot and leg. The operation was executed in December, 1785, the femoral artery being exposed a little below its middle, and surrounded by four ligatures drawn so gently as simply to bring the sides of the vessel together. "The reason for having four ligatures was," as is stated by Sir Everard Home, by whom the case was reported, "to compress such a length of artery as might make up for the want of tightness, it being wished to avoid great pressure on the vessel at any one part. The ends of the ligature were carried directly out of the wound, the sides of which were now brought together and supported by sticking-plaster and a linen roller, that they might unite by the first intention."

It is unnecessary to enter into any details respecting the after-treatment of the case. It will be sufficient for my purpose to state that on the second day after the operation the tumor had lost more than one-third of its original bulk; that the ligatures, some of which came away on the fifteenth day, excited severe inflammation in the artery, as well as in the surrounding parts; and that the man left the hospital on the 8th of July following, in good health, and with no appearance of any tumor in the ham. He subsequently resumed his former occupation as coachman, and died from an attack of remittent fever, fifteen months after the operation. The limb being dissected, the femoral artery was found to be impervious as high up as the profunda, while below the site of the ligatures, as far down as the tumor, it was open, and contained blood, except just where it entered the aneurism, where it was obliterated. The sac was a little larger than a hen's egg, but more oblong and flattened, and contained a solid coagulum adherent to its internal surface.

I have been induced to give a brief outline of this case for two reasons. In the first place, it deserves to be commemorated because it embodies the application of a new principle to the cure of a disease which, until then, was almost uniformly fatal; and, secondly, because it will enable us to establish, in a more satisfactory manner than we could otherwise do, the claims of Mr. Hunter to the credit of having originated the operation, which has been so sturdily denied him by the French surgeons, who have, almost with general consent, ascribed it to their countryman, Dominic Anel.

The case of Anel, which occurred at Rome in 1710, was that of a priest, who, from a prick of the brachial artery received in venesection, had an aneurism at the bend of the arm; the tumor was large, and apparently on the point of bursting. Having controlled the circulation in the limb by means of the tourniquet, he cut cautiously down upon the artery, and, after separating it from the accompanying nerve, raised it upon a hook, and tied it as near to the tumor as possible. All pulsation instantly ceased, the ligature came away on the eighteenth day, and at the end of a month the friar was able to use his arm as well as ever.

It will thus be perceived that the operations of the English and French surgeons differed from each other in every particular; and it is only surprising that there ever should have existed any contrariety of opinion respecting them. The procedure of Anel was executed for the cure of a traumatic aneurism; the artery was perfectly healthy, and it was tied as closely to the tumor as possible. He never supposed that he was about to establish a new principle in surgery; he nowhere alludes to any such intention; his only object seems to have been to afford his patient, who was suffering great agony, and who might bleed to death at any moment from the sudden bursting of his tumor, prompt relief. Hunter, on the contrary, had studied the subject with extraordinary care and attention; he had made numerous dissections, and even performed some experiments upon the inferior animals, as the dog and horse, with a view of ascertaining the condition of the artery in aneurism, and its ability to bear the ligature; and he had clearly perceived that, as the cause of failure of the old operation was that the ligation was always made too near to the tumor, the only safety would be to tie a sound portion of the vessel, even although this should be at a very considerable distance from the aneurism. His object was not to cut off the supply of blood at once, but simply to weaken its passage through the tumor, thereby giving its contents an opportunity of undergoing gradual coagulation, and at

the same time preventing the distal parts of the limb from perishing from the sudden stoppage of the circulation. The result of the case above detailed proved the correctness of his reasoning, and established, upon a firm and immutable basis, what is now universally recognized in Great Britain and in this country as the Hunterian operation for aneurism.

The operation of Hunter has been performed upon almost every artery of the body liable to suffer from aneurism. Even the aorta itself has repeatedly been tied; and, although all the cases have proved fatal, yet the result has been such as to show, most conclusively, that the event has been due much more to the injury inflicted upon the surrounding structures than to the violence done to the circulation by cutting off so great a quantity of blood from its accustomed channels. Remarkable simplicity now characterizes the operation; a healthy portion of artery is selected, great care is taken, in exposing the vessel, to disturb its sheath as little as possible, and only one ligature is used, but that is drawn so tightly as to divide the inner and middle tunics, when, a double knot being made, one extremity is cut off, and the other is brought out at the nearest point of the wound, which is then treated in the ordinary manner. In separating the artery from its accompanying vein or veins, the greatest possible care must be taken not to inflict any injury upon these vessels, as this would not only embarrass the operator, but might lead to severe phlebitis, and even mortification, especially in aneurism of the lower extremity. The procedure may generally be materially expedited and its safety insured by the cautious use of the grooved director, aided by dissecting forceps and the finger-nail.

Cessation of pulsation usually occurs at once upon tightening the ligature, although not necessarily so; sometimes, indeed, several days elapse before it is fully established, but even then it is commonly very much diminished in force, thus paving the way for the gradual formation of clots upon which the cure ultimately depends. The persistence of the circulation, after the main artery of a limb has been ligated, arises from the anastomosing branches continuing to pour their contents into that portion of the vessel which lies between the cord and the sac, as well as into the sac itself, and, perhaps, also into the distal portion of the artery. When these branches are inordinately large, or numerous, they may keep up such a supply of blood as to compromise effectually the success of the operation.

More or less pain usually attends the tightening of the ligature round the artery, if the patient is not under the influence of an anæsthetic. It is occasionally very severe; and cases occur, as when a nervous filament is included in the cord, in which there is a sense of tingling and of numbness.

The operation is generally followed by a slight diminution of temperature in the limb, but this rarely lasts beyond a few hours, when it is succeeded by a marked increase of heat, owing to the augmented activity of the cutaneous circulation, in consequence of the blood being forced principally through the superficial capillaries. Subsequently, however, as the anastomotic branches enlarge, and the circulation becomes equalized, the temperature sinks again, and now, perhaps, somewhat below the normal standard, the parts really feeling, for the first time, the loss of blood occasioned by the ligation of the artery. In not a few cases the limb retains its temperature after the operation with hardly any variation, as if nothing at all had happened.

Instead of using the ordinary silk ligature, Dr. Stone, of New Orleans, in 1859, in a case of aneurism, tied the common iliac artery with a silver wire, simply approximating the sides of the vessel, and leaving the wire in the wound, convinced of its entire harmlessness. The patient died on the twenty-sixth day, but, as no autopsy was made, the disposition of the ligature was not ascertained. At the Clinic of the Jefferson Medical College, in 1861, I secured, in a similar manner, the femoral artery in a case of popliteal aneurism; the patient rapidly recovered without any untoward symptom, and the wire still remains in the thigh, nearly the entire wound having healed by the first intention. Since that period I have operated, equally successfully, with the metallic ligature upon four other cases, the last of which concerned the external iliac. Dr. Bozeman, of New York, in 1867, tied the common carotid with the silver wire, and other vessels have been thus secured by other surgeons.

Experiments made upon the lower animals, on the ligation of arteries with silver wire, by Dr. B. F. Howard, of New York, fully substantiate the results obtained from its employment in the human subject. He has shown that when the wire is drawn tightly, it causes not only death of the portion of the artery embraced by it, as after ligation with a silk thread, but that the loop is cast off, and is either discharged at the surface, or becomes

encysted at some distance from the point of application. He, therefore, concludes that silver wire is not an innocuous material if the internal and middle coats of the artery are severed, but that, when applied so loosely as merely to obstruct the flow of blood through the vessel, it remains permanently at the point where it is placed, thereby greatly diminishing the risks of secondary hemorrhage.

In ligating an artery in its continuity for the cure of aneurism, the greatest possible care must be taken not to wound the accompanying veins, as such an accident inevitably endangers the issue of the case by provoking a bad form of phlebitis, from the effects of which few persons recover. The ligature, passed through the vessel, embraces a portion of it tightly along with the artery, and, consequently, acts precisely as a seton, causing diffusive inflammation not only in the vein itself, but also in the surrounding structures. The risk will be particularly great when an artery is tied close to the aneurism, as, during the progress of this disease, the inflammation of the sac not unfrequently extends along the connective tissue which connects the two vessels, thus rendering them specially intolerant of interference. When such an accident happens, the ligature must at once be withdrawn, and repassed with more care, either at the same point or a short distance above or below. The bleeding is not always easily arrested by compression.

However executed, the operation should never, if possible, be undertaken without some preliminary treatment. For a week or so previously, perfect rest both of the part and system should be enjoined, the diet should be carefully regulated, and proper attention should be bestowed upon the bowels and secretions. If there be any doubt in regard to the establishment of the collateral circulation, this desirable object should be promoted by compressing, for a few hours daily, the main artery of the limb. Mr. Charles H. Todd, of Dublin, in a paper on aneurism published in 1822, strongly insisted upon this mode of treatment, and expressed his conviction that, when neglected, the operation must often be followed by mortification and other bad consequences from the want of a due supply of blood in the distal portion of the limb after the application of the ligature. Compression, under such circumstances, would have the additional effect of favoring the solidification of the contents of the sac.

Mr. Syme suggested that, in aneurism of the carotid, axillary, gluteal, and iliac arteries, in which the Hunterian operation is not admissible, the sac should be freely opened, and, after evacuating its contents, the artery should be sought for, and tied above and below. In several instances in which he adopted this procedure, his efforts were crowned with complete success. The last case to which he applied it was one of aneurism of the external iliac, in which, after ripping open the sac to the extent of six inches, and turning out six pounds of blood and fibrin, he secured not only this vessel but also the common and internal iliac arteries, and had the satisfaction of saving his patient. Very little suppuration took place. Such operations are replete with interest, as showing the skill and daring of the surgeon, and the astonishing powers of endurance of the system, but are hardly to be held up as examples for general imitation.

Two grave objections may be urged against the adoption of this procedure. In the first place, the artery in the immediate vicinity of the aneurism is often so much diseased as to render it incapable of sustaining the slightest pressure of the ligature; and, secondly, it is frequently no easy matter to expose the vessel, owing to the manner in which it is overlapped by the expanded sac. Moreover, the sac, especially when of large size, is often fed by a number of arteries, the bleeding of which it would be extremely difficult to control by any mode of management that can be devised. The plan, however, should not, on these accounts, be entirely rejected, for it is easy to perceive that circumstances might arise where it would afford the only chance of safety. Many years ago, I operated upon a case of aneurism of subclavian artery, where, nearly one month after the ligation of the vessel, the sac burst into the chest and occasioned fatal pleurisy. If such an event could have been foreseen, the opening of the sac, and the evacuation of its contents, might have saved the patient's life.

In tying deep-seated arteries, especially those at the root of the neck, great advantage may often be derived from throwing reflected light, with the mirror of an ophthalmoscope, into the recesses of the wound. No operation of this kind should be performed on a cloudy day; and, after the division of the integument and muscles, the knife should be used as little as possible.

After-treatment.—The treatment after the Hunterian operation must be conducted with great judgment and attention. The patient being carried to bed, the limb is placed in an easy and relaxed position, but not elevated, lest arterial influx be interfered with; and

it will be well, especially if there be a diminution of temperature, to envelop it in cotton or flannel, aided, if necessary, with bottles of hot water, until it regains its natural warmth.   Cold applications must be carefully avoided, even if the skin is hot and swollen, as they tend to lower the vital powers, and so predispose to mortification.   A full anodyne should be administered immediately after the operation, to relieve pain and tranquillize the action of the heart; light diet, with cooling drinks, should be enjoined; and the temperature of the apartment should not be permitted to exceed 65° of Fahrenheit.   The bowels must not be opened for several days, and then only by the mildest laxatives, drastic purgatives being particularly objectionable on account of their tendency to cause excitement and throbbing of the arteries; occurrences which would inevitably be injurious after such an operation.   All bodily and mental exertion should be studiously guarded against for several days after the separation of the ligature, lest, the feeble adhesions giving way, secondary hemorrhage ensue.

Causes of Failure.—The causes of failure after the Hunterian operation are, first, violent inflammation, followed by mortification; secondly, death of the limb from deficiency of blood; thirdly, secondary hemorrhage, either from premature detachment of the ligature, or rupture of the sac; and, fourthly, maintenance of the circulation by means of a redundant anastomosis.

Ligation of an artery is not often followed by severe *inflammation* at the seat of the operation; the parts, indeed, frequently, if not generally, unite by the first intention, or, if there is any suppuration, it is chiefly at the seat of the ligature.   It is only, or mainly, in persons of bad constitution that the resulting action is apt to run riot, or to assume an erysipelatous character, threatening limb and life.

Mortification of the limb below the seat of the operation, from inflammation and defective circulation, is met with almost exclusively in the inferior extremities after ligation of the femoral artery for aneurism of the popliteal.   Of 156 cases of this operation, analyzed by Dr. Norris, 28, or about $5\frac{1}{2}$ per cent., were followed by this accident.   Of these cases, 11 died and 7 recovered, 6 of the latter having escaped with the loss of the affected limb.   The probability is that gangrene may arise from a mere want of blood in the parts, but most generally it is dependent upon inflammation of the artery leading to the formation of fibrinous clots, and the consequent closure of the caliber of the vessel and also of some of the collateral channels.   The mortification usually begins within the first forty-eight hours in the distal portion of the limb, from which it gradually spreads until the patient dies, as he usually does in from five to ten days after the first appearance of the disease.

The best means of averting this untoward occurrence is to place the limb in a proper position and to guard against overaction in the parts.   If gangrene manifest itself, notwithstanding our endeavors to prevent it, amputation must at once be performed, the limb being, if possible, removed above the seat of the aneurism.

Secondary hemorrhage after this operation is most liable to occur about the time of the separation of the ligature, but it may come on before or it may not take place until much later.   In general, it supervenes from the seventh to the eighteenth day.   A diseased state of the artery, excessive inflammation, or the malapplication of the ligature, may be considered as so many exciting causes of the accident.

The frequency of secondary hemorrhage after the Hunterian operation has been differently estimated by different writers.   Lisfranc collected 180 cases, of which 32 were followed by this occurrence.   In 530 cases analyzed by Porta, secondary hemorrhage took place in 73, of which more than one-half perished, either directly or indirectly from loss of blood.   If we descend to particular operations, it will be found that of 38 cases of ligation of the carotid there were 7 cases of secondary hemorrhage, with 2 cures and 5 deaths; the external iliac affords 8 cases out of 97, of which 5 died and 3 were cured. Of 187 operations upon the femoral artery, 19 were followed by hemorrhage, and of these 9 died and 9 were cured, the other recovering after amputation, rendered necessary on account of the persistence of the bleeding.

The principal remedies for secondary hemorrhage, after such an operation, are gentle but systematic pressure at the site of the bleeding, and also over the main trunk of the vessel, assisted by the internal use of acetate of lead and opium in union with ergot and aconite.   Occasionally it will be necessary to tie the artery higher up; or even to amputate, especially if, when the surgeon is called to the case, the loss of blood has already been great, and the parts are much obscured from swelling and infiltration.

Rupture of the aneurismal sac is uncommon after the operation.   It is observed chiefly in cases of long standing, where interference has been delayed on account of the neglect

of the surgeon or the obstinacy of the patient. The rupture may be caused either by the gradual absorption and attenuation of the sac, aided, perhaps, by the pressure of some bony prominence, or it may be due solely to the effects of inflammation. In the latter case, which is by far the more frequent of the two, the accident generally occurs at a comparatively early period after the operation, and is always preceded by well-marked local and constitutional symptoms, indicative of the impending mischief.

This accident hardly admits of satisfactory treatment. When the aneurism is favorably situated, the best plan is to lay it freely open, and to secure the main artery leading to it above and below the tumor. When this is impracticable, the chief reliance must be upon well-adjusted pressure, assisted by cold applications, Monsel's solution, and other means tending to moderate the force of the circulation.

A return of *pulsation* in the aneurismal sac, an occasional occurrence, is commonly due to a redundant collateral circulation, or an anomalous arrangement of the main artery leading to the tumor, as, for example, the high division of the femoral. In some cases it continues after the application of the ligature; in general, however, it comes on at a variable period, and now and then an instance arises in which it reappears several times during the progress of the after-treatment. The pulsation usually ceases spontaneously, followed by the gradual shrinking of the sac. When it continues obstinate, and the tumor either retains its former bulk or progressively enlarges, the remedy most likely to be successful is steady compression both of the aneurism and of the main artery of the limb. In popliteal aneurism, forced flexion of the leg might be tried.

None of these accidents, save the last, and that is a very improbable one, will be likely to happen if the part and system have been thoroughly prepared for the operation, if the disease has not made too much progress, and, finally, if proper care and judgment be employed in managing the case after the application of the ligature. Deligation of the carotid arteries for the cure of aneurism is liable to be followed by inflammation of the brain and lungs, with softening of the former of these organs and hepatization of the latter. Much of the mortality from the operation is attributable to these diseases. Cases have occurred in which this operation was followed by erysipelas, phlebitis, pyemia, tetanus, and apoplexy, but such results are extremely rare, and scarcely deserve to be taken into account in connection with it.

The subjoined table shows that the mortality after the Hunterian operation is truly frightful; a circumstance which should induce every one to regard it with suspicion and distrust.

Arteries.	Cases.	Deaths.	Per cent.
Innominate.	14	13	92.85
Subclavian	124	59	47.58
Carotid	106	37	34.90
Abdominal aorta	8	8	100.
Common iliac	32	25	78.1
Internal iliac	7	3	42.8
External iliac	126	35	27.77
Femoral	278	105	37.76
Total	695	285	41.

It is almost needless to state that such an operation should never be performed when the case is attended with great disorder of the general health, serious disease of an important internal organ, as the heart or lungs, or the coexistence of aneurism in any of the larger vessels, more especially if the concomitant lesion has already made unusual progress. Particular inquiry should always be made into the condition of the kidneys; for there is hardly any affection which exercises so prejudicial an influence upon recovery as albuminuria. Pregnancy is no bar to the procedure; and several instances have been reported in which the patients made an excellent recovery, and lived for a considerable period, after the deligation of a large artery for the cure of an aneurism complicated with aneurism of the arch of the aorta.

b. DELIGATION OF THE ARTERY AT THE DISTAL SIDE OF THE TUMOR.

It is well known that aneurism occasionally occurs so near the trunk as to render it impracticable to perform the Hunterian operation, or that the artery, although accessible at the cardiac side of the tumor, is too much diseased to support a ligature. Brasdor, of Paris, nearly a century ago, suggested the idea that gradual and efficient coagulation of the blood in the aneurism might be produced by placing the cord upon the artery

at its distal aspect. He had no opportunity, however, of solving the problem upon the human subject. The merit of this was reserved for Deschamps, although the case upon which he tried it could hardly have been worse for such an undertaking. The patient, besides being old, was worn out by suffering, and the tumor, which occupied the upper part of the thigh, extending to within a short distance of Poupart's ligament, was nearly seventeen inches in circumference. The operation was tedious and difficult, on account of the depth of the artery and the absence of pulsation, but the vessel was at length discovered and effectually secured. Contrary, however, to expectation, the aneurism, which had not made any marked progress for some time previously, now rapidly increased in volume, and on the fourth day, when it appeared to be on the point of bursting, it was resolved to perform the ordinary operation, notwithstanding the reasons which had just before been urged against its adoption. Two ligatures were applied, but the operation was attended with copious hemorrhage, and the man died at the end of eight hours.

The operation of Brasdor was next performed by Sir Astley Cooper, in a case of aneurism of the external iliac artery, extending so high up into the abdomen as to render it impossible to place a ligature between it and the heart. The femoral artery was, therefore, tied a short distance below Poupart's ligament, between the epigastric and profunda. The patient did well for some days, when the tumor, which had been gradually diminishing in volume, burst, causing death by hemorrhage.

What the results of these two efforts might have been, if the cases had been of a more favorable character, is a matter which must, of course, be left to conjecture. It is certain, however, that no attempt was made to repeat the operation until 1825, when, almost forgotten by the profession, it was performed by Mr. James Wardrop, of London, in a case of aneurism of the carotid artery. The success was complete. The ligation was followed by an immediate diminution of the tumor, which gradually progressed until, at the end of the fifth week, the neck had nearly regained its natural form; the ligature had dropped off, and the general health was entirely reëstablished. The patient, a woman, seventy-five years old, continued to be perfectly well three years after the operation.

Having been equally successful in several other cases, Mr. Wardrop was induced to extend the principle of Brasdor's operation to aneurism of the innominate artery. It

Fig. 326.   Fig. 327.   Fig. 328.
Hunter's.   Brasdor's.   Wardrop's.

occurred to him that, by tying one of the branches of this artery, the force of the circulation might be so far diminished in the tumor below as to cause the solidification of its contents. The patient upon whom he performed this operation was a woman, forty-five years of age, who had a pulsating swelling, of the size of a turkey's egg, in the inferior part of the neck, its base being concealed by the sternum, and evidently connected with the innominate artery. For the cure of this disease the right subclavian was tied in July, 1827, with the effect of a gradual amelioration of the distressing symptoms, and the ultimate disappearance of the tumor, its site being occupied merely by an unnatural hardness, the result, probably, of the remains of the aneurism. This was the condition of the patient fourteen months afterwards, at which time the carotid artery still pulsated, although not so vigorously as the left, and the woman was in better health than she had been for a long time.

The procedure now described constitutes what is called Wardrop's operation, although it is in reality, as was before intimated, merely an extension of that of Brasdor; and is only applicable to aneurism of the innominate artery. It has been performed within the last thirty years in a considerable number of cases, generally by tying the common carotid; but the results have, for the most part, been unfavorable, owing, as has been alleged, and as is probably the fact, to the occurrence of violent inflammation both in the aneurismal sac and in the vessels in immediate communication with it, terminating fatally in a few days, or, at most, in a few weeks.

Looking at the statistics of deligation of the artery at the distal side of the sac, however performed, we find that of 84 cases, death speedily occurred in 42. The majority of the patients who recovered were greatly benefited, and in not a few life was prolonged for several years.

The annexed cuts afford an illustration of the various methods of ligating arteries for the cure of aneurism, above described. A glance will serve to show how inefficient such an operation must be when performed according to the plan suggested by Mr. Wardrop.

c. INSTRUMENTAL COMPRESSION.

The treatment of aneurism by compression dates back to a very early period of the profession, and, although the principles upon which it was formerly conducted were far from being scientific, numerous cases have been published illustrative of its efficacy. It is not my design to inquire into the history of the operation, or to seek out its inventor for the purpose of awarding him praise for his ingenuity and enterprise; it is sufficient to state that the compression was originally applied directly to the tumor, or to the tumor and the limb upon which it was situated, either by means of an apparatus specially constructed for the object, or by a compress and roller, extended from the distal portion of the extremity upwards, beyond the seat of the disease. The practice was most frequently employed for the relief of traumatic aneurism, particularly that form of it consequent upon injury of the brachial artery, at the bend of the arm; and, although it proved occasionally successful, in not a few cases, it was followed by violent inflammation of the sac and limb, eventuating in ulceration, abscess, or gangrene.

The compression may be direct or indirect; that is, it may be applied either to the swelling itself, or to the artery upon which the swelling is situated. Aneurisms of various arteries, as the carotid, subclavian, brachial, iliac, femoral, and popliteal, were successfully cured by the former method by Fabricius, Tulpius, Acrel, Petit, Platner, Guattani, Ciniselli, Brunker, and many others; and, although the treatment is now obsolete, there is no doubt that it might still occasionally be advantageously employed, especially in tumors of small size. The compressing agents were generally pieces of sponge, agaric, or linen, confined by adhesive strips and a roller. Sometimes the pressure was rendered more firm by the interposition of a solid substance, as sheet lead, papier-maché, or sole leather. Dionis refers to a case in which a man cured himself of a false aneurism at the bend of the arm by keeping up gentle pressure upon the tumor for a year with a cushion.

In the latter part of the last century, Vernet, a French military surgeon, conceived the idea of curing aneurism by applying compression upon the artery immediately beyond the tumor, upon the same principle as that upon which Brasdor soon after suggested the use of the ligature. He thought that the operation was particularly adapted to aneurism situated so near to the trunk as to forbid a resort to the ligature, or compression upon the cardiac side of the swelling. It would appear, however, that he practised it only in one instance—upon a man affected with inguinal aneurism—and that so great was the disturbance which it created in the pulsation of the sac, that he was obliged, in a very short time, to abandon it. From the want of success attending the case, ill adapted as it was to test the principles of a new process, no one, it seems, felt afterwards disposed to make further trial of it, and it was accordingly forgotten, or remembered only as an ingenious sugestion.

The late Dr. J. M. O'Ferral, of Dublin, was a warm advocate of compression of the artery both above and below the tumor, or at its cardiac and distal aspects, and the signal success which attended the operation in three cases thus treated by him affords a strong argument in favor of its general adoption. As the coagulation of the blood in this method of treatment is the great desideratum, it is reasonable to conclude that it will be more rapidly effected when the compression is applied at two points than one, the blood within the tumor being thus brought more thoroughly and promptly into a state of repose so favorable to the accomplishment of the object.

Compression of the artery above the tumor, or between it and the heart, was first distinctly insisted upon as a remedy for the cure of this disease by the late Mr. Freer, of Birmingham, in his observations on aneurism, published early in the present century. In the work here referred to, he gave special directions for applying the compression, enjoining that it should be made by enveloping the whole limb with a bandage, and placing upon the vessel, in the most superficial portion of its extent, a small pad, which was then to be screwed down by means of a tourniquet. To render its action more

effective, a plate was secured to the opposite side of the limb, which, while it defended the integument and muscles from injurious constriction, concentrated the force upon the particular point of the artery where it seemed to be most needed. Notwithstanding this precaution, the application of the tourniquet was soon followed by pain and œdema of the extremity, generally so violent as speedily to necessitate its removal. Short, however, as the compression was, it occasionally laid the foundation of a cure, which was afterwards perfected by the steady but cautious use of the ordinary compress and bandage.

Acting upon the suggestions of Freer, Dupuytren and others applied themselves to this mode of curing aneurism, devising useful and ingenious instruments as substitutes for the more clumsy contrivance above described. The French surgeon, in particular, invented a most admirable compressor, at once simple and efficient, which still bears his name, and which he employed successfully in several cases of aneurism of the inferior extremity. The cures, however, that were effected in this way were few compared with the great number of failures, and the consequence was that the treatment never met with much favor. What added to the dissatisfaction of practitioners was that, in quite a considerable number of cases, it was followed by results highly prejudicial to the limb, if not both to limb and life.

Thus stood the treatment of aneurism by compression, when, in 1843, it was destined to experience a complete revolution in the hands of several eminent surgeons of Dublin, particularly Hutton and Bellingham, the latter of whom, in a short tract upon the subject, was the first to point out, upon correct and scientific principles, the manner in which it acts in curing the disease. Prior to this period, one replete with interest to the progress of surgery and humanity, compression was a very painful and hap-hazard proceeding, conducted without any discrimination and judgment, and, consequently, without any certainty as to its results. The idea was that, in order to succeed, it was necessary that it should be applied firmly and steadily, so as to arrest the circulation, and cause adhesion of the sides of the artery, very much as in the operation of ligation. Hence the poor patient was generally subjected to immense torture, often compelling the speedy discontinuance of the treatment, which, however, notwithstanding this, was occasionally followed by the worst consequences, as manifested in the violent swelling of the affected limb, and perhaps its ultimate loss by gangrene. The procedure was altogether a blind one, and, therefore, just as likely to prove prejudicial as useful. It was employed by one practitioner simply because it had occasionally been employed successfully by another, and not because any one had, as yet, been so fortunate to lay down any broad and definite rules of action. It was for this reason that it was so long in acquiring the confidence of surgeons ; that it was totally abandoned at one time, and resumed, with doubts and misgivings, at another. Its principles were not yet fully developed, or placed upon a just and comprehensive basis. This labor was performed by Dr. Bellingham and his able associates, who thus created a new era in the treatment of aneurism, hardly less brilliant than that of the ligature. What the ultimate fate of this treatment will be, time alone can determine ; that it is destined to supersede entirely, as some have predicted, the use of the ligature, is extremely questionable, and yet, considering the remarkable success which has attended it, such an occurrence seems not improbable.

Compression, as now conducted, is not only safe, but comparatively free from pain ; and, although it is often tedious, yet few cases will ultimately resist its influence. It is more especially applicable to the cure of popliteal aneurism, in which its greatest triumphs have hitherto been achieved, but it has also been successfully employed in aneurism of the femoral artery, both in its upper and lower extent, and in aneurism of the brachial artery, particularly at the bend of the arm. It is applied upon a sound portion of the vessel, at the cardiac site of the tumor, and generally at a considerable distance from it ; gently and intermittently, not firmly and persistently as in the old method ; just sufficiently to retard and weaken the circulation in the sac, not to arrest it, and so as to favor the gradual formation of clots ; allowing time for the development of the collateral vessels, and the maintenance of the nourishment of the distal portion of the member. Occlusion of the artery at the site of compression is not wished for ; on the contrary, it is desirable that the vessel should remain pervious, and retain as many of its normal properties as possible. As the stratification of the sac proceeds, as layer after layer of fibrin is deposited and becomes firmly cemented to that which preceded it, the hollow pouch is gradually filled up, and usually, along with it, also the upper orifice of the artery. To this rule, however, there are occasional exceptions, the blood continuing to flow from the artery in a

direct stream across the sac in a sort of ditch, groove, or
narrow channel.

For the purpose of making the compression, various in-
struments have been devised, one of the most simple and
efficient of which is represented in fig. 329; it is a modi-
fication of that of Charrière, and was successfully employed
by one of my former assistants, Dr. Thomas P. Gibbons,
in a case of aneurism of the popliteal artery. It consists
of a long, wide, concave, steel plate, supporting three semi-
circles of the same metal, arranged in two segments, which

Compressor.

slide upon each other, and are connected each at their free extremity with a screw and
pad. The whole construction of the instrument is such as to enable the surgeon to regu-
late the pressure with the greatest nicety; making it more or less firmly, and at one or
more points, or alternately at different points, as circumstances may seem to require. The
annexed drawings, figs. 330, 331, and 332, are added for the purpose of enabling the

Fig. 331.

Hoey's Clamp.

reader to avail himself of the use of other compressors, if the one here described should
prove inadequate. A compressor, almost identical with Hoey's clamp, will be found de-
scribed in the sixth volume of Mr. Benjamin Bell's Sur-
gery, published in 1788. It was invented by Mr. James
Moore, of London, and was originally designed as a com-
pressor of the principal nerves of the extremities, as a
means of preventing pain in amputations.

It will generally be well, if the patient is at all intelli-
gent and trustworthy, to instruct him in the use of the
instrument, so that he may regulate the compression ac-
cording to its effects; lessening it if it is productive of
pain, and conversely.   •

One important principle in the treatment is to com-
press the artery against the bone, as a point of support;
if the pressure is widely diffused, it will only serve to
embarrass the venous circulation, and to retard the cure.
The preliminary treatment should be the same as in the
Hunterian operation; and during the progress of the
cure the limb should be kept constantly bandaged from
its distal extremity upwards, to support the capillary
vessels, and thus prevent œdema. Strict quietude, both

Fig. 332.

Carte's Circular Compressor.

of mind and body, should be observed; the diet should be mild but sufficiently nutritious;
and free use should be made of aconite, opium, and acetate of lead, as suggested under

the head of the treatment of internal aneurism. If the case is very protracted, and the health is likely to suffer from the consequent confinement, gentle exercise may be permitted in the open air, the instrument being worn several hours in the morning and evening. If any considerable swelling arise in the limb, all treatment must be temporarily suspended, and measures adopted for the relief of the morbid action. To continue the compression under such circumstances would be to jeopard the safety both of the part and patient.

The period at which a cure may reasonably be looked for in this treatment is subject to much diversity ; in some instances compression for a few hours has sufficed to produce this event ; in others, and these embrace the great majority of cases, a number of days are required ; occasionally several weeks elapse ; and examples have been reported where the stratification and obliteration of the sac were not completed under two months. As a general rule, it may be assumed that, other things being equal, the cure will be more rapid in proportion to the small volume of the tumor, the tolerance of the part to compression, and the absence of complications.

Within the last few years the old method of treatment of aneurism by forced or steady, persistent compression has, with some modification, been revived, and is likely, in great degree, if not entirely, to supersede the gradual method, upon which, until recently, so much stress was laid. The credit of recalling attention to this plan of treatment is mainly due to Dr. William Murray, of Newcastle on-Tyne, who, aware of the great pain attending it, accompanied its employment with the administration of chloroform, thus paving the way to a new application of this invaluable anæsthetic agent. His case was one of aneurism of the abdominal aorta in a man twenty-six years of age. The tourniquet was applied to the vessel above the tumor on two distinct occasions, at an interval of three days ; on the first for two hours, without any material impression, and on the second for five hours, followed by the complete arrest of pulsation, and a rapid cure. The man survived the operation, performed in 1864, six years, when, dying from the effects of another aneurism of the aorta, an opportunity was afforded of verifying the correctness of the previous diagnosis, so that no doubt could be entertained about the success of the treatment.

Since the publication of Dr. Murray's case, a number of other examples, with equally gratifying results, have been reported by other observers. Thus, Dr. E. D. Mapother, of Dublin, in a case of ilio-femoral aneurism, succeeded in effecting consolidation of the tumor in four hours and a half, by compressing the common iliac artery. In another case—one of popliteal aneurism—the time occupied in arresting the pulsation was ninety-seven hours, although pressure was applied both at the proximal and distal sides of the tumor, the limb having previously been elevated and bandaged to interrupt the return of venous blood, and direct pressure made upon the sac with an elastic roller. Dr. Heath, of Sunderland, cured an aneurism of the external iliac artery by compressing the abdominal aorta for seven hours ; Mr. Lawson was successful in a case of inguinal aneurism by pressure continued for four hours ; and in another case consolidation was effected in twenty minutes. In a case reported by Mr. Russell, a cure took place in a few hours. In all these instances the use of chloroform was conjoined with the compression. That the exhibition of this anæsthetic, however, is not at all essential to success, although generally of inestimable service in preventing suffering, and thus rendering the patient comparatively comfortable during the treatment, is proved, first, by the case of Mr. Tait, in which he effected a cure of an inguinal aneurism by compression of the aorta partly with and partly without the aid of chloroform ; and, secondly, by one by Mr. Bannon, in which a popliteal aneurism was consolidated in six hours under the stupefying influence of a large opiate. In the case of a negro, twenty-seven years of age, recently under my care in the Jefferson Medical College Hospital, I succeeded in effecting consolidation of the contents of a femoral aneurism in four hours by compressing the common femoral artery with two bags of small shot, each of which weighed five pounds, which were kept steadily in place by a meniscus-shaped mass of lead weighing ten pounds.

The practice pursued in these cases, it seems to me, is worthy of general adoption, as it usually requires only a very short time to effect a cure, and is unattended with suffering. The success of the treatment, as originally planned and carried out by Dr. Murray, hinges entirely upon the complete arrest of the movement of the blood in the aneurismal sac, and its firm coagulation without the deposition of laminated fibrin, as generally happens in gradual compression. They prove, as the English surgeon justly affirms, that chloroform does not in the slightest degree interfere with the coagulation of the blood, and that, with the aid of this anæsthetic, the treatment is applicable to arteries in the most delicate and

sensitive situations in the body, without any danger from its protracted exhibition. Dr. Murray assumes, as a principle, that in all cases of aneurism of the larger arteries spring-ing from the aorta the best plan is to compress this vessel itself, experience having demonstrated its entire safety.

The results of the treatment of aneurism by instrumental compression are, on the whole, highly flattering, contrasting most favorably with those of the Hunterian deligation. Thus, of 124 cases of compression for popliteal aneurism collected by Mr. Holmes from the records of British hospitals for a period of ten years, 66 were successful, and 58 failed. None died, and there are, indeed, not more than five or six cases of death from the effects of the operation. On the other hand, of 77 cases of aneurism of the popliteal artery, treated according to the Hunterian principle, 11 died, or 1 in 7.

Besides its indisputable safety, compression, whether forced or gradual, has the advan-tage, if it fail, that it does not preclude the propriety of a resort to the ligature.

d. DIGITAL COMPRESSION.

Digital compression for the cure of external aneurism, originally proposed as a distinct measure, in 1846, by Professor Vanzetti, of the University of Padua, was first success-fully employed, a year later, by Professor Knight, of New Haven, in a case of popliteal aneurism, in which he cured his patient in forty hours, the compression having been maintained by a relay of assistants. During the past twenty years, this mode of treat-ment has attracted much attention, both in this country and abroad, and has been fully discussed in statistical papers, particularly by Broca, Verneuil, Petiteau, S. W. Gross, Abbadie, Gaultron de la Bâte, Barlemont, and Fischer.

In a series of communications in the Vierteljahrschrift für Praktische Heilkunde for 1869, Dr. George Fischer has given a statistical report of 188 cases treated by this method. As this paper contains a more full account of the subject than any other which has fallen under my notice, I shall freely avail myself of its contents.

It has been shown that digital compression has been successful where mechanical com-pression was unbearable, or had failed, whether alone or conjoined with other means, interrupted or continued, complete or incomplete ; it has even, in several cases, been applied by the patients themselves, and in these instances either a cure was effected, or the tumor was so modified that subsequent ligation or mechanical compression of the artery always resulted in recovery.

The pain produced by the pressure of the finger is not greater than that caused by the pad of an instrument ; should the point of contact become tender and inflamed, chalk, starch, or flour may be sprinkled upon the surface, or a thin, wet cloth may be interposed between the finger and the skin.   However this may be, suffering, both local and general, may easily be allayed by the free exhibition of anodynes, or by keeping the patient pretty freely under the influence of chloroform.

Of the 188 cases analyzed by Dr. Fischer, 124 were spontaneous and 64 traumatic aneurisms ; 13 were diffuse and 16 were varicose. The tumors were seated in 3 cases upon the iliac ; common femoral, in 7 ; femoral, in 8 ; popliteal, in 90; tibio-peroneal trunk, in 1 ; anterior tibial, posterior tibial, and external plantar, each, in 1 ; subclavian, in 1 ; axillary, in 4 ; brachial, in 32 ; radial, in 7 ; ulnar, in 1 ; superficial palmar arch, in 5 ; carotid, in 4 ; temporal, in 2 ; ophthalmic, in 6 ; supraorbital, in 1 ; and inferior coronary, in 1.

Of the entire number, 121 were cures and 67 failures, including 4 deaths : 104 cures were effected by digital compression alone, and 17 by compression aided by other plans of treatment : 33 cases which had resisted instrumental compression, and which ought not to have been treated by this process, are to be deducted from the 67 instances of failure, so that there remain 138 cases, with 104 cures by digital compression alone, thus affording 75.3 per cent. of success. In these cases, other methods of treatment, chiefly instrumental compression, had previously failed. Digital compression, preceded by instrumental com-pression, was unsuccessful in 19 instances.

One death was due to digital compression employed as the sole method of treatment. The case was that of a man, seventy-one years of age, affected with popliteal aneurism, which became solid at the end of twenty-four hours. Limited gangrene set in, under which he succumbed in two months. In three instances death ensued from the combined employment of the finger and apparatus.

The period required for the cure of aneurism by this method is much shorter than by any other known plan of treatment, except forced instrumental compression. When

employed alone from the very commencement, it frequently does not exceed nine or ten hours. Compared with ordinary instrumental compression, the length of time is most striking. According to Dr. Fischer, a cure, on an average, is effected in three days, whereas the mean duration of treatment by the latter method is fourteen days. The greatest objection to digital compression is the difficulty of procuring a sufficient number of competent assistants.

Dr. Boughter, of the Army, has reported in the Philadelphia Medical Times for October, 1871, the case of a soldier, twenty-four years of age, affected with a double aneurism of the femoral artery, in which the lower tumor, seated in Scarpa's triangle, was cured in five hours and a half by digital compression. No effect was produced upon the upper tumor, which extended slightly under Poupart's ligament, on the one hand, and, on the other, to within an inch and a half of the upper end of the lower sac. The pressure was made over the artery, or, rather, over the mouth of the proximal tumor, against the brim of the pelvis, and was resumed for six hours, at the expiration of four days, with the view of obliterating the latter. Slight diminution in size alone resulted.

In all cases of this operation in which the consolidation of the tumor occurs rapidly, as, for instance, within a few hours after the commencement of the treatment, it is obvious that it must be brought about simply by the coagulation of the blood, without any effort at fibrinous stratification, as always happens when the cure is gradual.

e. DIRECT COMPRESSION OF THE DENUDED ARTERY.

Direct compression of the denuded artery as a means of cure in aneurism has been practised at different periods by different surgeons with a degree of success, in the main, highly flattering and worthy of repetition. Among the earliest operations of this kind are those of Birch, Dubois, Cline, Foster, Deschamps, Percy, Assalini, and Monteggia, near the close of the last and the commencement of the present century. As the original proceedings were more or less rude, it is not surprising that they were occasionally followed by violent inflammation, secondary hemorrhage, and even death. They consisted in exposing the artery at a sound portion of its extent, and surrounding it with a ligature tied over a cylinder of linen, wood, cork, or agaric, retained until the sides of the vessel were supposed to be firmly adherent to each other. Mr. Birch, of London, in 1786, in a case of femoral aneurism, inclosed the artery in two cords, only the lower one of which was tied, the upper one remaining loose, to be tied in the event of accident or secondary hemorrhage. The operation was followed by severe inflammation at the wound, and the aneurism burst on the twelfth day, death occurring soon after. Cline, in a case of a similar kind, employed two broad tapes, one lying behind the other, the outer embracing a piece of cork. Deschamps invented what he termed a serre-artère—a kind of double canula—with which the artery was looped in a manner very similar to that of snaring a nasal polyp with the canula of Levret. A temporary ligature, ligature d'attente of the French surgeons, was placed underneath the artery, above this instrument, to be used in the event of hemorrhage from ulceration of the vessel. Percy employed a pair of forceps with two flat surfaces; while Dubois preferred what is called a presse-artère. Scarpa surrounded the artery with two stout, flat ligatures, the ends of which were tied over a small linen cylinder, six lines in length by three in diameter, the wound being afterwards filled with charpie. Professor Assalini, in the early part of the present century, in a case of popliteal aneurism, successfully employed an instrument very similar to that of Percy, consisting of two short silver blades, united by a rivet, the degree of pressure being regulated by a screw passed through the handle of the instrument. Assalini, as Hodgson informs us, subsequently treated two other cases in a similar manner, the clamp in each being removed at the end of twenty-four hours, without any return of pulsation.

Mr. Crampton, of Dublin, in 1814, in a case of popliteal aneurism, exposed the femoral artery, at the usual site, by an incision three inches in length, and arrested the pulsation with a narrow tape arranged in such a manner as to admit of being tightened or relaxed at pleasure without interfering with the wound. At the end of two hours and a quarter, when the cord was gently slackened but not entirely loosened, all pulsation in the aneurism had ceased. In twenty-four hours the compression was taken off; but, as a measure of precaution, the ligature was retained a day longer. The tumor by the fifth day had decreased one-half in size, and was not only free from pulsation, but almost incompressible. On the eighteenth day the wound was completely cicatrized. Dease, soon after, in a similar case, removed the ligature at the end of twenty-four hours. Travers, of London,

in 1817, tied the brachial artery in a case of traumatic aneurism at the bend of the arm, the ligature being taken away at the expiration of fifty hours. A single noose was employed. The pulsation in the tumor at once ceased, and a complete cure followed without any accident.

The primary object which these surgeons had in view in performing the operations here described was to bring about the consolidation of the contents of the aneurism by retarding and diminishing the flow of blood, precisely in the same manner as in the Hunterian method. In addition to this, some, at the head of whom was Scarpa, aimed at the same time to effect occlusion of the compressed artery by the division of its lining membrane, in the hope of being thus able to favor the effusion of plasma and the adhesion of the contiguous surfaces.

In the modern method the object is to remove the ligature, clamp, or forceps from the artery the moment it is ascertained that there is complete consolidation of the contents of the aneurism. To effect this to the best advantage and in the safest manner, the artery is exposed at the Hunterian site of the tumor to an extent only of a few lines, and inclosed in a single ligature of iron wire, without the addition of the underlying cylinder employed in former times. The best contrivance for the purpose is a flat, metallic button, about one inch and a half in diameter, with two central apertures for the reception of the extremities of the ligature. The wound being closed in the usual manner, the ligature can be tightened or slackened according to circumstances. The pressure may generally be safely removed by the end of the first day.

The value of this operation, as now performed, is still undetermined. I am myself favorably impressed with it. In a case of femoral aneurism, under my charge in 1869, in a man fifty years old, recovery ensued without a single untoward occurrence, the ligature having been removed at the end of the second day. The operation saves time, does not cause much disturbance at the seat of ligation, and is not likely, with proper care, to be followed by secondary hemorrhage, the great danger after such a proceeding. The chief objection to the employment of the wire is the difficulty of detaching it. If a cylinder, as, for example, a piece of gum-elastic catheter or adhesive plaster, be used, it should be placed in direct contact with the skin, the wound having previously been thoroughly closed, otherwise the pressure might provoke severe inflammation, if not ulceration and secondary hemorrhage.

Acupressure of the denuded artery may be substituted for the ligature, wire-loop, or forceps; but it does not appear, from the few trials that have been made of it to possess any special advantages. Mr. Henry Lee refers to a case of small traumatic aneurism of the ham cured by this method. Dr. Cheever, of Boston, has applied it successfully to the femoral artery in popliteal aneurism, but in a second case death resulted from mortification; and Professor Porter, of Dublin, acupressed unsuccessfully the axillary artery in a case of subclavian aneurism.

f. FORCED COMPRESSION WITH THE ELASTIC BANDAGE.

In aneurisms of the extremities forced compression of the arteries leading to and from the seat of the disease has not infrequently succeeded. The treatment is a recent device, first practised, in 1875, by Surgeon Walter Reid, of the English Navy. The compressor employed is Esmarch's bandage. This is applied quite firmly, at first, to the distal side of the tumor, commencing at the extremity of the limb, and reaching as high up as the swelling; it is then carried loosely over the latter so as not to compress it; and, when it has reached its proximal side, it is again applied firmly for a short distance, when the rubber tubing or band is wound round the limb with sufficient tightness to arrest the circulation in the sac, and the bandage is removed. The compression is maintained for a period varying from three-quarters of an hour to three hours and a half, or until there is reason to believe that the contents of the aneurism are completely solidified. As the pain, attendant upon the operation, is often very severe, the patient should, for at least a portion of the time, be kept under the influence of anæsthesia; and, lest the clotted blood should be washed away after the removal of the tubing, the compression should be continued for some hours longer with an ordinary instrument or by means of the finger. The great efficiency of this operation is due mainly, if not entirely, to the arrest of the circulation through the collateral channels as well as through the main artery, thereby securing absolute stagnation of the contents of the sac.

Dr. S. W. Gross has collected seventy cases of aneurism thus managed. The seat

of the disease was the popliteal artery in fifty-three instances, the femoral artery in ten examples, the anterior tibial in two cases, and the posterior tibial, the internal circumflex, the external iliac, the brachial, and the axillary artery, each, in one case. Of the entire number thirty-nine were cured, twenty-seven failed, and four died. In the four cases in which death followed the treatment, the sac and tributary artery were occupied by recent clots. In the successful cases pulsation was perceived in the tumor on the removal of the tubing, but remained permanently absent after the continuance of several hours of digital or instrumental compression. The chief danger after this operation is from gangrene of the limb from the size or extension of the clot. The four deaths were due to gangrene in two, to collapse and impending gangrene in one, and to collapse with rupture of an aneurism just above the pad of the tourniquet in one.

g. FORCED FLEXION.

Fleury, a French military surgeon, it would seem, originally suggested the idea that forced flexion might be beneficially employed in the treatment of aneurism of the extremities; a suggestion which was first successfully practised in 1852, by Thierry, of Paris, in a case of traumatic aneurism at the bend of the arm. In 1857, Maunoir, of Geneva, availed himself of this treatment for the cure of a large aneurism of the ham; and shortly afterwards the treatment was successfully employed by Mr. Ernest Hart, of London, through whose writings it became known in Great Britain and in this country. It is chiefly applicable to aneurism of the ham and of the bend of the arm, although it has also been successfully employed, by Dr. Gurdon Buck and Dr. Eldridge, in aneurism of the groin, and it might, possibly, be practised in aneurism of the axilla. The principle of the treatment consists in moderating and retarding the flow of blood in the tumor, as for instance, in the lower extremity, by bending the leg forcibly upon the thigh, so as to approximate the heel to the buttock, and confining it there by means of a strap, the limb being previously enveloped in a bandage. The patient need not be rigidly confined to bed, but may occasionally sit up, and even exercise on crutches. Pain and stiffness of the limb may be diminished with inunction of oil and chloroform. Care is taken to move the knee occasionally, lest ankylosis should occur. The cure is commonly very tedious, from three to six weeks being required for the complete arrest of the pulsation, and in a number of the cases in which this treatment has been pursued it has signally failed; in several, the patient was unwilling to bear the restraint which it imposed, and in one at least it was followed by rupture of the sac into the joint, necessitating the ligation of the femoral artery. In a case of popliteal aneurism, the volume of a small fist, in a man nearly forty years of age, a patient at the College Clinic, I effected a cure by forced flexion in less than twenty-four hours.

It is obvious that this mode of treatment, which commends itself chiefly by its great simplicity, is more likely to succeed in small and recent aneurisms than in large and old, in which it must of necessity be occasionally attended with failure. Indeed, it can hardly be considered as applicable to the latter class of cases, as it might induce rupture of the sac, or even be productive of gangrene of the leg.

Of 106 cases of popliteal aneurism, treated by forced flexion, the statistics of Dr. Fischer and Liégeois, afford 45 cures and 54 failures, the successful issues in 29 of the former cases having been obtained with the aid of other methods. 7 cases died from rupture of the sac.

h. GALVANO-PUNCTURE.

It would seem that this operation for the radical cure of aneurism was first suggested, in 1832, by Mr. Benjamin Phillips; so far, however, as my information extends, it was not practised by him upon the human subject, and the idea had been almost lost, when, about thirty years ago, it was revived, principally through the agency of Pétrequin, of Lyons. The operation is founded upon a knowledge of the fact that the galvanic current has the effect, if properly directed, of coagulating the blood as it circulates through the different parts of the body. It is executed by means of two long, slender steel needles, introduced into the aneurismal sac at right angles, and in such a manner as to touch each other, their heads being then connected with a battery of large electro-motor force. The action of the battery is maintained uninterruptedly for a period varying from ten to twenty-five minutes, according to the tolerance of the part, and is usually required to be several times repeated. When the tumor is large, the number of needles is increased, and the direction of the current frequently changed, so as to afford a better chance for

the formation of clots. As the operation is generally very painful, it is proper that the patient should be placed under the influence of anæsthesia during its performance. Moreover, as there is danger of seriously charring the integument, and thus endangering the sac by mortification, the needles should be carefully coated, in a part of their extent, with gum-lac. The success of the procedure is enhanced by compression of the artery above and below the tumor, thereby preventing the clots from being washed away, before an opportunity has been afforded them of becoming consolidated and united with each other and with the walls of the aneurism. The after-treatment consists in the application of ice to the part, in perfect quietude, and in the administration of a full anodyne, to tranquillize the action of the heart and arteries.

Experience has not fully determined the value of this mode of treatment. That it is liable to occasional failure is sufficiently evident from the unsuccessful cases that have from time to time been published in England and on the continent of Europe. On the other hand, a considerable number of cases have been reported in which its employment was followed by a perfect cure. Of 50 cases, collected by Ciniselli, in 1856, in which the operation had been practised, 23 were successful, 20 failed, and 7 died. Examples of cure, by this method, of aneurism of the aorta, the brachial, subclavian, popliteal, and external iliac arteries, have been reported by different observers since that period, and, doubtless, others have occurred of which I have no knowledge.

Galvano-puncture is not only painful, but far from being devoid of danger. In some of the reported cases it produced severe inflammation and even suppuration of the sac, followed by great swelling of the limb, together with excessive constitutional disturbance, threatening the destruction both of the part and system. The operation is, therefore, a hazardous one, and on this account should never be attempted without due consideration of its consequences, especially when the aneurism is large, and situated at, or near to, the trunk. Coupling this circumstance with the want of success of the operation, and the severe pain attending its execution, not to say anything of the danger of producing sloughing in the skin and sac by the action of the galvanic fluid as it is being transmitted from the battery to the tumor, it is questionable whether it is worthy of repetition, notwithstanding the high estimate placed upon it by Pétrequin, Burci, and some other surgeons. The force of this conclusion derives additional support from the facts collected by Boinet, that in seven of the successful cases, above referred to, compression and ice were employed simultaneously, thus creating a just doubt whether these agents had not as much to do with the cure as galvano-puncture, if, indeed, not more.

i. INJECTIONS.

Attempts have been made in modern times to effect the radical cure of aneurism by the injection of certain fluids with a view of favoring the concretion of the blood, the consolidation of the sac, and the obliteration of the affected artery at the seat of the disease. The practice was originally suggested, early in the present century, by Professor Monteggia, of Milan, who proposed the use of solutions of acetate of lead, tannic acid, and other astringents, as, in his opinion, well adapted to the purpose, although he never, it would seem, performed the operation. His idea was that, by throwing these substances into the sac, so as to bring them fully into contact with the blood within, it might be possible to provoke the rapid formation of coagula, and thus effectually arrest the circulation. He supposed, moreover, that the remedy might occasionally be advantageously combined with Brasdor's operation and with compression of the artery upon the cardiac side of the tumor, applied by means of a tourniquet or some other suitable instrument, very much as it is

Fig. 333.
Pravaz's Syringe.

performed at the present day. The suggestion of the Italian surgeon, however, received little, if any, attention until within a comparatively recent period, when it became the subject of numerous experiments upon the inferior animals, as the sheep, dog, and horse, principally by the French practitioners, who, after having tried various articles have at

length been induced to give a decided preference to a concentrated solution of perchloride of iron in water. The fluid is introduced into the sac by means of a small glass syringe, invented by Dr. Pravaz, of Lyons, and represented in fig. 333. The piston is moved slowly by means of a screw, not more than five or six drops of fluid being thrown into the sac, that quantity having been found to be amply sufficient for the purpose. As it takes at least half a minute before the blood can be made to coagulate, during which the heart performs not less than thirty-five pulsations, it is necessary to keep the contents of the tumor perfectly quiet, while the injection is progressing, by compression of the artery immediately above and below the aneurism.

The operation is generally productive of severe pain, and as it is liable to be followed by considerable inflammation, it often becomes necessary to make use of antiphlogistic measures, both locally and constitutionally. Its repetition must be governed by circumstances; if everything passes off well, and the sac is promptly solidified, no further interference will, of course, be demanded; but, if the reverse be the case, a similar quantity of the solution is thrown in at the end of the third or fourth day, in the same cautious manner as before. The slightest inflammation of the tumor contraindicates the repetition of the injection.

Since 1853, when Pravaz first published the results of his experiments on animals, a number of cases have been reported in which injections of perchloride of iron have been employed in aneurism of different parts of the body, as well as in aneurism of different kinds, as spontaneous, traumatic, and varicose. The arteries upon which the disease occurred were the supraorbital, carotid, brachial, ulnar, femoral, popliteal, and tibial. More recently the treatment by injection has been extended to aneurism of the innominate artery by Barrier and Eliot, of the subclavian by Pétrequin, and of the aorta by Syme and Hutchinson, but in no instance with success.

Although a few cures have been effected by this treatment, such is the great risk of inflammation, suppuration, and even gangrene, both of the sac and of the surrounding structures, that it is extremely questionable whether any prudent surgeon should repeat it. Of eleven cases, reported by Malgaigne in 1854, it is announced that four had proved fatal, that every one had had bad symptoms, and that only two had been successful. This statement alone, if true, as no doubt it is, is sufficient to condemn the operation as unsafe, and to render its adoption improper in the face of the more unexceptionable methods of ligation and compression. The great desideratum is to discover an article, which, while it shall promptly coagulate the blood, will not cause any severe irritation in the sac and parts around it. It has been supposed that the acetate of the peroxide of iron might have this effect, but, although at least one successful cure by its use has been reported, it has not been tried sufficiently often to enable us to pass any definite judgment upon its true merits. I should myself have more confidence in the efficacy and safety of subsulphate of iron than in any other preparation of this metal. It is perfectly destitute of caustic properties, and is the most prompt and efficient coagulator of the blood at present known.

At a meeting of the Philadelphia Academy of Surgery, in 1882, Dr. W. W. Keen reported the particulars of a case of aneurism of the palm of the hand, in which an injection of ten drops of diluted Monsel's solution caused rapid mortification necessitating amputation of the lower part of the forearm.

Subcutaneous Injection of Ergotine.—The subcutaneous injection of ergotine, in view of its influence in provoking contractions of organic muscular fibres, has been employed in a few instances of aneurism, and the results have been so far favorable as to warrant its further trial. Professor Von Langenbeck, with whom the practice originated, has reported the case of a man, forty-two years of age, who had been affected with an aneurism of the radial artery, of the size of a hazelnut, for twenty years. The injection of about three grains of ergotine between the skin and the tumor, was followed, in twenty-four hours, by its complete subsidence. It reappeared momentarily, in consequence of a slight effort made by the patient, but had entirely vanished at the end of eight days. In a second case, one of subclavian aneurism, of the size of a fist, in a man, aged forty-five years, about thirty grains were injected in the course of six weeks, at intervals of three days, and in quantities varying from half a grain to three grains. The tumor was somewhat shrunken, the pulsations were sensibly weakened, and the pain and paralysis of the arm and hand were diminished to a remarkable extent.

j. ACUPUNCTURE, AND INSERTION OF FOREIGN MATERIALS.

The idea of curing aneurism by acupuncture seems to have first suggested itself to the fertile mind of Velpeau, who ascertained by experiments upon dogs that, if needles be thrust into an artery, the blood manifests a tendency to form clots around them, which, in a short time become so firmly adherent as to cause more or less obstruction in the circulation. He thought that this plan might be applied to the treatment of aneurism, but this was not done until 1831, when it was successfully employed in a case of carotid aneurism by Mr. Benjamin Phillips, of London. In 1879, Mr. Christopher Heath inserted three pairs of fine sewing needles into a traumatic subclavian aneurism, for which he had amputated at the shoulder-joint two months previously. The needles were withdrawn on the fifth day, and the tumor became solid. After death from bronchitis, the aneurism was found to be nearly filled with dense fibrin. In a case of ilio-femoral aneurism recorded by Dr. Macewen, acupuncture conjoined with proximate compression proved successful. In view of the limited experience with the procedure, it is difficult to form an estimate of its value; and this is particularly true of the cases of Heath and Macewen, in which the other measures employed probably contributed greatly to the success.

Under this head may be briefly mentioned *caloric puncture*, a process originally employed in 1825, by Sir Everard Home, under the supposition that the application of heat would favor the coagulation of the blood. His case was one of aneurism of the external iliac artery, for which he had twenty-eight days previously tied the superior portion of the femoral. He inserted a solitary needle into the tumor, and then heated its head with the flame of a spirit lamp. The pulsation became somewhat weaker under the application, but the tumor was not lessened by it. A second application was made six days after, with a large needle, retained for thirty-five minutes. The pulsation greatly diminished in force, and the contents of the tumor seemed to be solidified. Three days later, however, the pulsation recurred with its accustomed freedom, a circumstance which suggested a third trial. At the end of twenty minutes all pulsation had ceased and did not reappear afterwards.

Mr. Moore, of London, in 1864, in a case of large aneurism of the arch of the aorta, projecting across the ribs, and almost ready to burst, attempted to induce coagulation by means of the introduction of a large quantity of fine iron wire, altogether twenty-six yards in length. It was inserted through a delicate canula, and deposited in every direction in the sac. Rapid coagulation was the consequence. Violent inflammation, however, soon ensued, pulsation recurred in the tumor, and the man died exhausted on the fifth day after the operation.

The procedure suggested by Mr. Moore has been imitated by Domville, Murray, Levis, Bryant, Stimson, Maury, Montenovesi, and Bacelli, the materials used having been iron wire, catgut, horsehair, or watch springs. It has proved to be utterly useless, and is tedious and difficult of execution.

k. MANIPULATION.

The treatment of aneurism by manipulation was first formally proposed, in 1852, by Sir William Fergusson. It consists in the forcible squeezing of the tumor, with the intention of breaking up its fibrinous contents, in order that some of the fragments thus detached may be carried by the circulation into the distal extremity of the artery, thereby closing its orifice, and so effecting a radical cure. The first case in which the treatment was tried was one of aneurism of the right subclavian artery, seated partly within and partly on the outside of the scalene muscles, the tumor being about the size of a hen's egg. The sac being emptied of fluid blood, its sides were forcibly rubbed against each other, with the immediate effect of an arrest of pulsation in all the vessels in the limb below. The pulsation, however, returned in about seven hours, and the manipulation was accordingly repeated the next day with a similar result, but it was not until the end of a week that any permanent impression appears to have been made upon the circulation. The tumor now gradually diminished in size, and everything gave promise of an ultimate cure, when suddenly, seven months afterwards, the patient was seized with violent fever attended with excruciating pain in the part, and died after a few days' illness. Although the axillary artery was found, on dissection, to have been blocked up, the tumor, instead of being obliterated, not only remained hollow, but had extended downwards over the axillary plexus of nerves, the pressure upon which had probably caused the excessive pain which immediately preceded dissolution. In another instance, also treated by Fergusson, the

result was more fortunate, but the cure was not finally effected until towards the end of the second year. Dr. Little, in 1856, obliterated by this means an aneurism of the right subclavian artery.

In a case of popliteal aneurism, reported in 1859 by Mr. Teale, of Leeds, this plan of treatment was successfully conjoined with digital compression. After the latter had been carried on for some time, with, apparently, very little effect, a portion of clot was detached, leading at once to the consolidation of the tumor. The late Professor Blackman, in a case of large femoral aneurism, was equally fortunate. In 1872, Herbert Page, of England, treated a case of popliteal aneurism successfully by this means.

Although no opportunity has presented itself to me of trying this plan of treatment, it is, I think, extremely questionable whether it ought to be repeated. The great objections to it are, first, the uncertainty of the operation, even when the distal end of the artery has been blocked up; secondly, the tardiness of its progress; and, thirdly, the danger that some of the detached clots may find their way into the brain, as in aneurism of the neck, thus causing fatal apoplexy, as has already happened in several cases in which the method has been tried. If employed at all, therefore, it should be restricted to aneurism of the subclavian, axillary, femoral, and popliteal arteries, in the early stage of the disease, before the tumor has acquired any considerable bulk; and the treatment will be so much the more likely to be successful if the circulation in the tumor be kept in check for some hours by pressure upon the cardiac side of the artery.

l. OPERATION OF OPENING THE SAC.

For the reintroduction of this operation, known as the operation of Antyllus, one of the most delicate, difficult, and hazardous that can be undertaken, the profession, as stated in a previous page, is indebted to the late Professor Syme, who did so much to advance practical surgery. It consists, as the name implies, in laying open the sac, turning out its contents, and ligating the diseased vessel above and below the tumor. The procedure is mainly applicable to aneurism of the arteries of the extremities, particularly the femoral and popliteal, to the former of which it has been successfully applied by Mr. Gay, Mr. Birkett, and Mr. Cooper Forster, and to the latter by Mr. Henry Smith; but it has also been performed for aneurism of the common carotid, axillary, and external iliac, as in the remarkable case of Mr. Syme, in which, for an enormous tumor of the last vessel, he tied the common, internal, and external iliac arteries, after having turned out six pounds of coagulated blood and fibrinous concretions. The patient recovered from the operation, but died in three months from another disease. In 1875, Dr. Frothingham, of Ann Arbor, in a case of traumatic aneurism of the common carotid artery, turned out the clots, and tied the artery at both ends, the operation being followed by a perfect cure.

One great danger of this operation is from hemorrhage, which may be so rapid, excessive, and overwhelming as to render it impossible to control it before it proves fatal. Another source of danger is from the resulting inflammation, which must necessarily be very great when the tumor is large and of long standing, and liable to be followed by profuse suppuration, if not ulceration and gangrene. As yet, the number of cases of this operation is too limited to justify us in pronouncing a final verdict in regard to its value. Indeed, even the particular class of cases to which it is applicable has not been determined.

The first point in such an operation is to guard against hemorrhage by means of the tourniquet or the elastic bandage, or, if this be impracticable, by digital compression. In Mr. Syme's celebrated case, the circulation in the aorta was controlled by an instrument passed around the abdomen, and the patient, consequently, lost hardly any blood. In laying open the sac, the proper plan undoubtedly is to make, at first, as suggested by the Scotch surgeon, a very small incision, an incision barely sufficient to admit the fingers, and then to enlarge it gradually until the whole hand can be insinuated, which thus answers as a plug to the wound while the fingers are pressed firmly against the orifices of the diseased artery so as to restrain the escape of their contents. As soon as the flow of blood is fully arrested, the aneurism is freed of its clots and concretions, and the artery tied above and below, or at its cardiac and distal extremities, the latter precaution being essential to the prevention of hemorrhage by the recurrent circulation. The application of the ligature will be greatly facilitated if, as was originally practised by Antyllus, and lately by Mr. Birkett, of Guy's Hospital, a probe, bougie, or director be introduced into the vessel, to serve as a guide to the knife, which cannot be used with too much caution,

inasmuch as the artery is often overlapped, to a considerable extent, by the aneurism, and cannot be properly exposed without a most delicate and tedious dissection. Any undue oozing from the inner surface of the sac may readily be arrested by the use of Monsel's salt.

The after-treatment must be conducted with special reference to the avoidance of secondary hemorrhage, high inflammation, erysipelas, and pyemia. The suppuration must necessarily be often very profuse, and it is, therefore, impossible to be too zealous in the use of detergent and deodorizing lotions, fresh air, and a properly regulated diet.

m. VALSALVA'S TREATMENT OF INTERNAL ANEURISM.

Internal aneurisms, inaccessible to the ligature and compression, occasionally recover under a regular and systematic course of treatment designed to promote the coagulation of the blood in the interior of the tumor, by increasing the plastic properties of this fluid, and quieting the action of the heart and arteries. This treatment, which was originally suggested by Valsalva, and which still bears his name, consists in the strict observance of the recumbent posture, perfect mental quietude, the occasional abstraction of blood from the arm, and the use, simply, of a sufficiency of food and drink to prevent starvation. When, writes Morgagni, Valsalva had taken away as much blood as was deemed necessary, he diminished the diet " more and more every day, until only half a pound of pudding was taken in the morning, and in the evening half that quantity, and nothing else except water, the weight of which was also regulated, and which he medicated with what is called quince-jelly, or the lapis osteocolla, ground down into a very fine powder. After the patient had been sufficiently reduced by this method, so that he could scarcely raise his head from the bed, to which, by Valsalva's direction, he was confined, the quantity of aliment was day by day increased, until the strength that was necessary to enable him to get up had returned."

Whether Valsalva effected any cures by this method of treatment is not known; if he did, they must have been very few, as the plan is, with one or two exceptions, founded upon entirely erroneous principles, frequent venesection, and a very reduced diet, almost carried to starvation, being anything but conducive to the fibrinization of the blood in the aneurism, by which alone the alteration of the sac can be essayed. Indeed, experience has shown that the only true course to be pursued is the physiological one, in which the abstraction of blood is scrupulously abstained from, at the same time that a sufficient amount of food is allowed to prevent that irritability of the system which is always sure to arise when the body is for any length of time imperfectly nourished. The quantity of solid food should not be less, on an average, in the twenty-four hours, than from nine to twelve ounces, consisting of equal parts of hashed meat and bread, potato, or rice, at dinner, with a suitable quantity of stale bread, toast, or cracker at breakfast and supper; tea, coffee, and all other drinks, excepting water, lemonade, and milk, as well as all kinds of condiments, being strictly avoided. The patient should be kept perfectly at rest, in the recumbent posture, with the mind in as tranquil a state as possible, while the system should be steadily maintained under the use of tincture of aconite, or of veratrum viride, conjoined with acetate of lead and opium; or, what would be better, as more likely to promote fibrinization of the blood, ergot and subsulphate of iron. The pulse should be brought down, if practicable, to forty-five or fifty beats in the minute, and the chances of success would be all the greater if a prolonged state of somnolency could be maintained, the patient sleeping the greater part of the twenty-four hours. Protracted constipation of the bowels should be aimed at; if purgatives become indispensable, they must be of the mildest character, as all irritating and griping articles are sure to do harm by exciting the action of the heart and arteries.

The length of time during which this treatment should be continued must vary according to the circumstances of each individual case, and no attempt should, therefore, be made to reduce it to any general principles. It certainly might, with judicious management, be kept up, without detriment, for a number of consecutive weeks, if, indeed, not several months. As the patient emerges from it, he should return, very gradually and cautiously, to his accustomed diet, except that, for a long time afterwards, it should be free from all stimulants; nor should he, for a similar reason, take any, except the most gentle, exercise. In short, everything should be done to second nature in her efforts to effect the cure thus auspiciously begun, and which, other things being equal, will always be so much the more likely to take place if the aneurism is small and of recent standing.

My opportunities for treating abdominal and intrathoracic aneurisms according to the plan here sketched have not been sufficiently extended to enable me to form anything like a correct estimate of its value. In the cases in which I have employed it, although the patients seemed to be materially benefited, so far as pain was concerned, and the pulse was brought down below fifty, the progress of the disease was apparently not at all retarded. It is proper, however, to add that all the cases were far advanced when they fell into my hands. Professor Tufnell, of Dublin, in 1874, reported a number of instances treated upon this principle, in which permanent cures were happily effected. In a case reported by Mr. Head, in 1877, an aneurism of the innominate artery, apparently in a very unfavorable condition, was successfully relieved by this method. Pelletan, Surgeon to the Hotel-Dieu, of Paris, in the early part of the present century, obtained remarkable results from the Valsalvian method: he conjoined with it the application of ice, or of cold and astringent lotions, and a number of his cases were either partially or completely cured by it. Roux also had a successful case of aneurism of the thoracic aorta.

To sum up the modern medical treatment of internal aneurisms, the essential points consist of perfect tranquillity of mind and body, absolute confinement in the recumbent posture, a restricted diet, consisting principally of solids, a retarded circulation, and a healthy state of the blood.

When the cause of the disease is a syphilitic taint of the system, the most reliable internal remedy undoubtedly is iodide of potassium, either alone or in union with mercury, in doses, at first, of eight or ten grains thrice a day, gradually increased to fifteen or even twenty grains, according to the tolerance of the stomach. Excellent cures are occasionally effected by this remedy in cases even apparently more or less desperate.

n. GENERAL MEDICAL AND SURGICAL TREATMENT.

Persons affected with aneurism often experience, as stated elsewhere, great pain and other suffering, both from the inflamed condition of the tumor and from the pressure which it exerts upon the surrounding parts. In aneurism of the thoracic portion of the aorta and of the arteries at the root of the neck, the pain and dyspnœa are sometimes excessive, demanding prompt and vigorous measures for their relief. If the patient is plethoric, and the pulsation in the tumor uncommonly active, the loss of six, eight, or even twelve ounces of blood will be useful, but care must be taken not to carry the venesection too far, otherwise injurious reaction may take place, and thus aggravate the suffering. When the tumor is accessible, or situated externally, whether partly or entirely, the blood is often most advantageously abstracted directly from the part by means of leeches, which, even when employed only in small numbers, generally afford immense relief, both as it respects the pain and the difficulty of breathing. Topical depletion is always extremely serviceable in inflamed aneurism, and it is here also that fomentations and refrigerating lotions, simple or medicated, come into play, frequently exerting their happiest influence. The choice of these remedies must be governed in these, as in other cases, by the tolerance of the part and system. Attention to position and rest must be enjoined, and strictly carried out. The bowels are not neglected, but great care is taken to avoid active purgation, experience having shown that this always produces undue excitement of the vascular and nervous systems. Anodynes are always well borne in these cases, and are often indispensably necessary to relieve pain and promote sleep; they should be administered in full doses, either alone or in union with diaphoretics and expectorants, according to the condition of the skin and of the respiratory organs. Any complications that may arise during the progress of the disease, whether self-existent or dependent upon the irritation produced by the pressure of the tumor, must be treated upon broad general principles.

When an aneurism becomes diffused, by parting with its fluid contents, in consequence of the partial destruction of its sac, whether by ulceration, gangrene, or rupture, the case at once assumes an additional importance, inasmuch as the occurrence greatly increases the patient's danger. In internal aneurism little is to be done in the way of treatment, under such circumstances, beyond attention to the circulation, the moderation of the force and frequency of which may, perhaps, assist in prolonging life, and, occasionally, there is reason to believe, even in effecting a radical cure by promoting the formation of coagula. When the disease is seated in an extremity, as the thigh or leg, and the tumor is of comparatively small size, without any tendency to gangrene in the distal portion of the limb, the proper plan unquestionably is, either to tie the main artery, or to arrest the circulation in the tumor by rapid and forcible compression while the patient is under the influence of anæsthesia. In this way, further extravasation will be prevented, and the

case will be likely to progress favorably. If, on the contrary, the tumor is of immense size, the limb hugely swollen, and the pulsation completely arrested; or if, in addition to all this mischief, there is marked gangrene, the only safety is immediate amputation at a suitable distance above the aneurism.

FALSE ANEURISM.

A false aneurism is a pulsating tumor formed external to the affected artery, and, consequently, without any aid whatever from its tunics. A number of affections, of a very opposite character, have been described under this appellation, and much confusion has been the result. To remedy this evil, I shall limit myself, in the account which I am about to give of the disease, to two varieties of false aneurism, the arterial and arteriovenous, the tumor in each being strictly circumscribed, and connected, in the former, with an artery, and, in the latter, both with an artery and a vein. What is called a diffused aneurism is, in fact, as stated elsewhere, no aneurism at all, but simply an accumulation of blood in the subcutaneous and intermuscular connective tissue, which, although it may be somewhat condensed around it, does not, in reality, in the true meaning of the word, constitute a proper aneurismal sac.

The most common cause of the spurious arterial aneurism is external injury, as a stab or puncture, such, for example, as was formerly so often inflicted in venesection at the bend of the arm, permitting the blood to escape in small quantity into the surrounding connective tissue, which is soon condensed into a firm, circumscribed, pulsating cyst, often not exceeding the volume of a pullet's egg, and of a rounded or ovoidal figure. Similar effects occasionally follow the laceration of an artery, as that of the ham, from the sudden and forcible extension of the leg, from the intrusion of the sharp end of a broken bone, or from ulcerative action.

Sometimes the aneurismal formation is secondary; that is, consequent upon the partial cicatrization of the wound, the interposed or overlying plasma being unable to withstand the impulse of the blood, and so yielding before it. However induced, all the tunics of the artery are at once perforated, and the blood is sent abroad into the circumjacent connective tissue, in the manner and with the effect just stated.

The sac in this variety of aneurism, formed originally out of the neighboring connective tissue, is speedily strengthened by the effusion of plastic matter, so that, in time, it often acquires considerable thickness, with an extraordinary degree of density. A number of cases have been under my observation in which the cyst, even at an early stage of the disease, was of a very firm, compact, fibroid consistence, and of a white, glistening appearance, its substance being convertible, by dissection, into several distinct strata. The tumor, particularly in cases of long standing, generally contains well-organized concretions, arranged in the same concentric manner as in the true sacculated aneurism, and presenting a similar hue and consistence. The course, symptoms, and termination of this disease do not require any special notice, as they do not differ, in any respect, from the ordinary form of the affection.

The treatment may be conducted by compression, or, this failing, by ligature. The compression is applied, as in true aneurism, upon the cardiac aspect of the tumor, four, six, or eight inches from it, with the instruments already described, retardation of the circulation and gradual obliteration of the sac being steadily kept in view. If an operation becomes necessary, a free incision is carried across the tumor, and a ligature applied immediately above and below, as in an ordinary wounded artery. The tumor may then be dissected out, or, as some prefer, although I think improperly, it may be left to the influence of the absorbents. As a preliminary step, a tourniquet is cast around the limb, to control the circulation in the affected vessel. Although one ligature is occasionally sufficient to effect a cure in this disease, it is always best to ligate the vessel both above and below the swelling, lest trouble should arise on account of the recurrent circulation, and thus lead to the necessity of doing at a subsequent period what ought to have been done in the first instance. The memorable case of Anel affords an excellent illustration of the fact that an aneurism of this kind, especially when seated at the bend of the arm, may occasionally be cured by one ligature applied just above the tumor.

1. The *arterio-venous* aneurism, originally described under the name of varicose aneurism, is a tumor situated, as the term implies, between a contiguous artery and vein, so as to admit of a ready interchange of the two kinds of blood. The most common site of it is the bend of the arm, as seen in figs. 334 and 335, where it is generally caused by a puncture in bleeding, in which the overlying vein, usually the median basilic, is

completely transfixed along with the superficial wall of the brachial artery.   A similar accident may, of course, happen in any other part of the body, from a stab or wound of a contiguous artery and vein, as between the femoral, or the aorta and vena cava; and, what is remarkable, the disease occasionally does not show itself until long after the infliction

Fig. 334.
Varicose Aneurism ; External Appearance.

of the injury.   Thus, Roux relates a case in which an arterio-venous aneurism formed at the bend of the arm four years after venesection; and Rokitansky observed a similar tumor in the axillary artery and vein thirty years after they had been struck by a shot. Sometimes, again, the aneurism forms in consequence of ulceration, beginning in one vessel and gradually extending to the other, and so eventually establishing a communication between them through the intervention of a sac.   Dissection has proved that such a connection may take place in deeply-seated as well as in superficial veins.   In a case described by Schottin the aneurism existed between the radial artery and the cephalic vein; and in one seen by Charnal it had formed between a deep vein and the brachial artery.

Fig. 335.

Varicose Aneurism ; Internal View.   a. The Artery.
b. The Vein.   c. The Intermediate Cyst.

A remarkable case of arterio-venous tumor, altogether unique in character, in which the cyst was formed by the expansion of the component structures of a nerve, has been reported by Mr. C. H. Moore, of London.

In whatever manner the aneurism is formed, the cyst is usually of small size, seldom exceeding, and not often equalling, that of a pullet's egg.   It is composed partly of condensed connective tissue and partly of plastic matter, the latter always greatly predominating, as is shown by its extraordinary thickness as well as density, which closely resembles that of the fibrous tissue.   The aneurism, although seldom very painful, always interferes more or less with the functions of the affected limb.   As the opening of communication is always very small, the blood rushes into it with a peculiar noise, not unlike that produced by the buzzing of a fly in a paper box, or the purring of a cat. Sometimes the sound is of a whirring character, similar to the prolonged articulation of the letter R.   It is perceived both by the ear and finger, and is so extraordinary that it may be regarded as pathognomonic.   The sac rarely contains any well-formed fibrinous concretions, and, hence, it is generally found to be perfectly smooth, white, and glistening, like the interior of an artery.   Manifesting little disposition to increase, it may remain stationary for years, and seldom, if ever, undergoes spontaneous cure, or terminates in rupture, ulceration, or grangrene.

When the tumor is very small, not exceeding the volume of a filbert or a pigeon's egg, and does not occasion any suffering, interference is neither desirable nor proper; it is merely an inconvenience, and had better be let alone.   The reverse, however, is usually the case, and then the same treatment will be required as in spurious aneurism connected with an artery only; that is, the vessel is tied immediately above and below the tumor, which is either left to undergo absorption, or, what is often preferable, it is carefully dissected out; an operation which, if performed with the aid of the elastic bandage, is generally bloodless.

Digital compression of the artery above the sac and of the opening leading from the sac to the vein should be employed before resorting to harsher measures.   Of fourteen examples, in at least six of which the above method was employed, eleven were cured.   In a case of varicose aneurism of the brachial artery Vanzetti succeeded in effecting a cure in six hours.

When the disease occurs in connection with the aorta and vena cava, operative interference will, of course, be out of the question; nor can anything be hoped for from medical treatment. The case, in fact, is irremediable, and will be sure eventually to cause death, either by the gradual giving way of the sac, or by exciting violent irritation, pain, and constitutional disorder.

2. *Aneurismal varix*, fig. 336, consists in a direct communication between a contiguous vein and artery, without the intervention of a sac; it differs, therefore, essentially from a varicose aneurism, in which, as has just been seen, there is always a distinct cyst, formed

Fig. 336.
Aneurismal Varix.

out of the surrounding tissues, along with more or less plasma. The affection is altogether so unlike aneurism, whether true or spurious, that it is surprising it should ever have been included in the same category.

The cause of aneurismal varix—a disease first described by Dr. William Hunter, in 1756—is usually some external injury, such as a puncture, transfixing a vein and piercing the contiguous wall of an underlying artery. Hence the lesion is most common at the bend of the arm, between the median basilic vein and brachial artery, in consequence of venesection. It may, however, occur between other veins and arteries lying in juxtaposition with each other, either through accident, or from the effects of ulceration commencing in the coats of one vessel and gradually perforating those of the other. In fact, it has been noticed in all the larger vessels, as the carotid and jugular, the subclavian, and axillary, the aorta and vena cava, the iliac, femoral, popliteal, and tibial. Several cases have fallen under my observation in which the disease followed upon amputation of the thigh. The orifice of communication is usually small, and of a circular shape, with well-defined margins, although there is, in this respect, no particular uniformity. The adhesion between the two vessels is generally very firm, as well as of considerable extent, and it is well that it should be so, otherwise there would be constant danger of the connection giving way. Owing to the incessant interchange and commingling of the two kinds of blood, the vessels gradually undergo important changes, the most interesting of which are that the vein assumes the properties of an artery, and the artery those of a vein. The vein, from the impetuous manner in which the arterial blood is sent into it at each stroke of the heart, becomes greatly enlarged both above and below the abnormal opening, at the same time that it acquires an extraordinary degree of density, and pulsates with unusual force. In the arm, in which I have met with a number of instances of this disease, I have found the dilatation of the vein to extend, on the one hand, nearly as high up as the axilla, and on the other, as low down as the middle of the forearm. The artery, which now receives black blood, but not in any large quantity, is eventually transformed into a soft, thin, flexuous tube, which, possessing the properties of a vein rather than those of an artery, pulsates but feebly under the finger.

The formation of this disease is generally attended with some degree of pain and swelling, along with interstitial effusions, causing the integument to pit slightly on pressure. The parts below the seat of the lesion are imperfectly nourished, and hence they usually feel somewhat cold and numb until the circulation is fully reëstablished through the agency of the collateral branches. As the blood passes from one vessel into the other, it produces a peculiar jarring sensation and a singular whirring noise, not unlike the purring of a cat, which often extends to a great distance along the dilated vein, now performing vicariously the functions of an artery, and which may be regarded as the pathognomonic signs of the disease. Occasionally a distinct tumor of considerable bulk is formed, consisting mainly of enlarged and tortuous veins.

In most of the cases of this lesion that have fallen under my observation, the inconvenience has been so trifling that I have not considered it proper to resort to operative interference. In one instance the patient had an aneurismal varix on the right arm from venesection performed upwards of fifteen years previously, and, although he was a black-

smith and a hard-working man, it did not in the least interfere with his occupation. Cases of aneurismal varix in different parts of the body, in which the disease remained station-ary for fourteen, twenty, thirty, and even thirty-five years, are mentioned by Hunter, Pott, Bell, Guattani, Scarpa, Breschet, Dupuytren, and other writers.

Several instances have been recorded in which a spontaneous cure is said to have taken place, but such an event must necessarily be very uncommon. The inconvenience caused by the pain and throbbing, which are often very distressing, may generally be greatly miti-gated by the steady and persistent use of an elastic bandage or stocking, as in the treat-ment of varicose veins of the extremities. When the parts are hot and inflamed saturnine lotions will be of benefit, especially if combined with rest and elevation of the parts. Cases in which a cure was effected by steady systematic compression have been recorded by Guattani, Monteggia, Oldknow, Samuel Cooper, and others.

The surgical treatment of this variety of aneurism has, within the last few years, ac-quired new interest from the fact that in nearly every instance in which the so-called Hunterian operation has been employed, the result has been fatal, the immediate cause of death being gangrene, or secondary hemorrhage, or a union of both. The cases of Physick, Atkinson, Mott, Charles Bell, Dupuytren, Harris, Baron, Fleischer, Morrison, and others, sufficiently attest the danger of surgical interference in this form of aneurism, especially when the disease is chronic, and accompanied by great enlargement of the vessels, extend-ing far beyond the original seat of the affection. Even, however, in recent cases, ligation of the principal artery is by no means devoid of risk, since the effect is to deprive the parts in the distal portion of the limb of an amount of blood which they can ill spare. Another source of danger in all cases of aneurismal varix is the diseased and attenuated condition of the arteries, causing their coats to yield readily under the slightest pressure of the ligature. Finally, I may mention, as another source of risk after the Hunterian operation, the difficulty which the blood experiences in forming a firm clot, owing to the fact mainly, if not exclusively, that blood is still freely sent into the artery by the associate vein after the application of the ligature.

The danger of secondary hemorrhage after such an operation is well illustrated in a case of aneurismal varix, in the stump of the thigh of a man, twenty-eight years of age, for whose relief in 1870 I ligated the femoral artery a short distance below Poupart's ligament. The thigh had been amputated six years previously by the circular method, three inches above the knee. The stump was eleven inches in length, very conical, greatly atrophied, and the seat of constant throbbing pain, rendering the use of an artificial limb impracticable. The femoral artery and vein were greatly enlarged as high up as the brim of the pelvis, while the vein, just above the end of the stump, was expanded into a convo-luted pulsating tumor, nearly the size of an ordinary fist. Pressure upon the artery below the groin completely arrested the pulsation in the tumor and also the aneurismal thrill. A vertical incision two inches in length, commencing twelve lines below Poupart's ligament, exposed the artery, which was then cautiously isolated, and encircled with a silk ligature loosely tied over a cylinder of adhesive plaster resting upon the skin exterior to the wound, which was united by four sutures. The object of this procedure was to remove the liga-ture as soon as a firm clot should form, but no clot of any kind was developed, and the man died, completely exhausted, of repeated attacks of hemorrhage, nine days and a half after the operation, the first bleeding having occurred at the end of the sixth day.

In view of all these circumstances,—the changed condition of the bloodvessels, the imperfect circulation in the distal portion of the limb, the difficulty of obtaining a firm clot after the ligation of the main artery, and the fact that patients thus affected occasionally live for many years in comparative comfort, with the additional knowledge that a spon-taneous cure now and then occurs, and that the disease if left to itself, rarely causes death— I am satisfied that the Hunterian operation for the relief of aneurismal varix should be abandoned as an unjustifiable measure. In desperate cases involving the distal portion of a limb, and attended with intolerable suffering, amputation is, of course, the only resource.

SECT. VII.—ANEURISM OF PARTICULAR ARTERIES.

ANEURISM OF THE THORACIC AORTA.

The merest glance at the situation of this vessel is sufficient to impress us with the great importance of its relations, and to show that any deviation from its normal con-dition, however slight, may be productive of the most fatal consequences.

The disease may exist, 1st, as a fusiform expansion; 2dly, as a dilatation of the coats of

the vessel, affecting the greater portion, if not the whole, of its circumference; or, 3dly, as a true, false, or mixed aneurism, properly so called, of variable size and shape, generally connected with the anterior or lateral aspect of the artery, the posterior being seldom implicated. The ascending portion and arch of the aorta, especially the latter, are by far the most frequent seats of the disease, owing to their vicinity to the heart, which thus imparts to them its impulsive and expansive movements, and to their greater proneness to fatty and other degenerations, rendering their tunics weak and brittle, and, consequently, liable to laceration. Of 703 cases, collected by Dr. Sibson, of London, 87 occurred in the arch of the aorta within the pericardium, and 193 on the outside of this bag. The ascending and transverse portions were affected in 140 cases; the transverse alone in 120 cases; and, conjointly with the descending aorta, in 20 cases; the descending portion of the arch in 72 cases; and the vessel below the arch in 71 cases. The aneurism is generally of the true species, commencing as a sac-like enlargement, which, as it increases, usually inclines to the right side of the chest, and is capable of acquiring a volume equal to that of a double fist. It is soon occupied with organized clots, which occasionally, though very rarely, accumulate to such an extent as to lay the foundation of a spontaneous cure. The opening of communication between the tumor and the artery varies in size from that of a dime to that of a twenty-five cent piece.

The disease is more common in men than in women, and not unfrequently arises at a comparatively early age, as from twenty-five to thirty, in consequence, apparently, of severe straining and other bodily exertion. Mr. Hutchinson has reported a case of aneurism of the arch of the aorta in a girl four years old, probably due to ulceration caused by the pressure of an abscess. Sailors and mechanics are peculiarly liable to the disease. The remarkable frequency of aneurism of this vessel is shown by the tables of Mr. Crisp, embracing 915 cases, of which 382 affected the thoracic aorta.

The duration of thoracic aneurism varies from a few months to upwards of three years, the average being from nine to twelve months. The tumor usually bursts into the left pleura, pericardium, trachea, bronchial tubes, œsophagus, or posterior mediastinum; sometimes into the heart, lungs, or spinal canal; and sometimes, again, but also very rarely, externally. Dr. Darrach, of Illinois, has shown by an analysis of twenty-three cases that aneurism of the descending aorta terminates pretty uniformly by rupture, while that of the arch generally ends by exhaustion and irritation, or some concomitant disease of the heart, brain, lung, or kidney. Occasionally the tumor gives way when it is not larger than a pullet's egg. Fig. 337 represents an aneurism of the arch of the aorta which had burst into the trachea.

Fig. 337.

Aneurism of the Arch of the Aorta opening into the Trachea.

The *symptoms* of aneurism in this situation are chiefly of a mechanical character, arising from the pressure of the tumor upon the surrounding structures. They consist mainly of pain, cough, dyspnœa, dysphagia, enlargement at the sterno-clavicular region, and of various kinds of sounds, synchronous with the action of the heart.

Pain, from the constancy of its occurrence, is a symptom of great value. It comes on early in the disease, is more severe in sacculated than in fusiform aneurism, and is evidently dependent, at first, or so long as the tumor is comparatively small, upon the pressure which the aneurism exerts upon the spinal and sympathetic nerves, and afterwards upon this cause and upon the erosion and perforation of the tissues, especially the sternum, ribs, and vertebræ. It varies much in degree, character, and situation. In the earlier stages of the disease it is most conspicuous on the left side; it is sharp, lancinating, and intermittent, not unlike the pain of neuralgia, darting about in different directions; at one time into the neck and face, at another through the chest and spine, now along the shoulder and arm, and now through the diaphragm and even the loins. As the tumor enlarges, and, by its pressure, erodes the neighboring structures, the pain becomes more steady, fixed, and severe; it gradually shifts to the right side, and is generally of a burning, gnawing, or boring character.

Cough is also a common symptom; it generally begins early in the disease, and is liable to severe exacerbations, often productive of intense suffering. It is of a crowing, stridulous, or ringing character, and obviously depends upon the irritation caused by the pressure of the tumor upon the air-passages. Sometimes it is short, spasmodic, and laryngeal.

The dyspnœa is always more or less distressing, especially when the disease has made

considerable progress, and is invariably aggravated by severe bodily exertion, as in walking up a hill, or ascending a flight of stairs. It is occasionally extremely violent, although the tumor may not exceed the size of a walnut, owing to the pressure which it exerts upon the trachea, or the trachea and bronchial tubes. During the latter stages of the complaint, the breathing is always so difficult as to prevent the patient from lying down, perhaps for days before he expires.

Dysphagia is seldom present until after the disease has made considerable progress, although it is sure, in the end, to become a prominent symptom; so that, ultimately, the sufferer finds it very difficult to swallow anything either in the form of food or drink.

Derangement of the functions of the stomach is frequently present, manifesting itself in a sense of fulness and oppression; flatulence, acidity, and eructations, evidently dependent upon the pressure of the sac upon the pneumogastric and sympathetic nerves. Now and then there is obstruction of the thoracic duct from the direct pressure of the tumor, interfering with nutrition, and aiding in the production of the peculiar cachexia so common in the latter stages of this disease.

It is not often that there is any external tumor, except when the aneurism points in front of the chest, as it frequently does in its latter stages, after it has partially destroyed the sternum and the ribs, or the ribs and intercostal cartilages. In the great majority of cases it shows itself on the right side of the chest from three to four inches below the collar-bone, as a pulsating swelling, lifting up the integument synchronously with the contraction of the heart, furnishing a distinct bellows, sawing, or purring sound, and being exquisitely tender on pressure. Occasionally the sac projects into the neck above the fourchette of the sternum, inclining towards the right sterno-clavicular articulation. When this is the case, it must necessarily overlap the innominate, common carotid, and subclavian arteries on the right side, and may even so effectually compress them as to cause their obliteration, although such an event is very unusual.

A distinct aneurismal sound, or purring tremor, is usually perceptible at an early stage of the disease, although it is extremely difficult, if not impossible, always to refer it to its proper source. It is synchronous with the beat of the heart, and gradually becomes more and more faint as the disease advances, in consequence of the progressive filling up of the sac by coagula.

Among the less constant symptoms are, palpitation of the heart, wheezing, panting, or asthmatic respiration, tracheal and bronchial râles, sense of constriction of the chest, œdema and lividity of the face, permanent contraction, or, more rarely, dilatation of one of the pupils, feebleness and irregularity of the pulse at the wrist, from the pressure of the tumor upon the innominate or subclavian artery, and anasarca of the extremities, especially the inferior. Alteration of the voice is by no means uncommon, and occasionally amounts to complete aphonia. In the more advanced stages of the disease there is also frequently an enlarged and varicose state of the subcutaneous veins over the upper part of the chest, generally towards the right side.

The *diagnosis* of intrathoracic aneurism is often extremely difficult; for, although the disease manifests itself by numerous symptoms, there is not a single one that can be considered as absolutely reliable. It is not surprising, therefore, that it should frequently terminate fatally, without any suspicion as to its true nature. Such an error will be most likely to happen when the tumor is small, or when it bursts into some neighboring canal before it has sensibly encroached upon the walls of the chest. As it increases in volume, its character becomes daily more and more apparent, and all doubt must, of course, vanish when the tumor points externally, although even then a careless practitioner might regard it as an abscess, and under this supposition, be perhaps even induced to open it, as I have known in two cases, notwithstanding the heaving and pulsating nature of the swelling, and the existence of all the other signs of aneurism. When the aneurism arises from the summit of the aorta, the tumor projects into the root of the neck, and may, in fact, ascend so high up as to simulate aneurism of the innominate or carotid artery. From this, however, it may generally be readily distinguished by the history of the case, by the impossibility of tracing with the finger the lower boundary of the tumor, by the dulness on percussion of the upper part of the chest, and by the presence of a larger amount of dyspnœa than usually attends cervical aneurism, particularly in its earlier stages.

The auscultatory signs rarely afford any conclusive evidence of intrathoracic aneurism. Few surgeons are able to discriminate between the sounds of the heart and those of such a tumor, and the difficulty must necessarily be much increased when, as not unfrequently happens, aneurism and cardiac disease coexist. When the heart is sound, and the aneurism has attained a considerable bulk, the diagnosis will be less ambiguous; but even

then it will require a very practised ear to detect the varying shades of difference. The sound of a thoracic aneurism is more like the purring of a cat than the clear murmur attending the first sound of the heart, and its distinctive features are still further defined by the presence of a peculiar tremor or vibratory movement. In the sacculated variety of the affection, it is often impossible to distinguish any abnormal sound whatever; at first, because of the small size of the swelling, and subsequently, because the tumor is filled with coagula, impeding if not preventing, the transmission of sound. In fusiform aneurism, and also in simple but extensive dilatation, the sound characteristic of the disease is generally easily recognized throughout its entire progress.

Gastric disturbance is generally a prominent symptom of intrathoracic aneurism, and occurring in association with dysphagia, is a sign of great value. Dr. Walter F. Atlee recently called attention to long-continued obstinate eructation as a symptom of much significance. He attended a gentleman for eighteen months on account of what appeared to be simply a rebellious attack of dyspepsia, accompanied with the most distressing flatulence and eructation. Death occurred suddenly and unexpectedly from the rupture of a circumscribed aneurism of the thoracic aorta not larger than a walnut.

Dulness on percussion, in a marked degree, can exist only in the event of the tumor being of considerable bulk; a small aneurism may be present, and even prove fatal, without any change of resonance. When there is dulness, it is always most conspicuous at the upper and middle parts of the chest.

Sometimes valuable diagnostic information may be derived from the displacement of the heart by the tumor, its pulsations being perceived in an abnormal position, where there is no evidence of pleuritic effusion or disease of the lungs to account for the change.

The precise situation of an intrathoracic aneurism is frequently, if not generally, indicated by the character of the functional disturbance. Thus, when the suffering is chiefly laryngeal, the inference is that the innominate artery, or the posterior and inferior portion of the arch of the aorta, is involved. Excessive pectoral constriction is caused when the tumor compresses the cardiac plexus, as when it springs from the ascending portion of the arch. Dysphagia denotes pressure either upon the œsophagus or upon the pneumogastric nerve, and a corresponding situation of the aneurism. When the disease produces bronchial asthma and orthopnœa, the probability is that the tumor involves the commencement of the descending portion of the arch. Permanent contraction of the pupil is caused by compression of the sympathetic nerve, as when the aneurism, arising from the superior and posterior part of the arch of the aorta or its primitive branches, projects backwards into the chest and neck.

Dr. W. T. Gardiner, of Edinburgh, who has carefully studied the nature of these functional disorders, states that "all aneurisms coming within the range of physical diagnosis, and not attended by any of the above symptoms, must necessarily arise either from the descending aorta, below the range of the pulmonary plexus, or from the upper part of the arch, projecting upwards and forwards; as it is in these situations alone that a thoracic aneurism can attain sufficient bulk to be discoverable, without involving important internal structures, and leading to very marked functional disturbance."

Among the affections with which aneurism of the thoracic aorta is most liable to be confounded are malignant tumors of the chest, especially sarcomas and lymphomas, abscess of the neck and of the anterior mediastinum, disease of the heart, as hypertrophy and valvular derangement, and aneurism of the innominate, carotid, and subclavian arteries. The best security against error will be an attentive consideration of the history of the case, and a thorough study of its progress, time often throwing more light upon the character of the malady than the most elaborate auscultatory explorations.

Dr. Drummond, of New Castle, England, has drawn attention to a sign, which, if verified by future observation, may prove to be of great value in determining the diagnosis of thoracic aneurism. It is based upon the fact that when the patient takes a deep inspiration, and then closes the mouth and expires slowly through the nose, short, puffing sounds are heard, synchronous with the systole of the heart, on auscultation of the trachea. The phenomenon is supposed to be due to the sudden systolic expansion of the sac compressing the lungs and forcing out the air.

The *treatment* of intrathoracic aneurism resolves itself into the adoption of measures to relieve the patient's sufferings rather than to cure his disease, of which there is, in any event, hardly even a remote possibility. If plethora exist, an occasional bleeding cannot fail to ameliorate, at least for a time, the pain and difficulty of breathing. The circulation should be controlled by perfect quietude of mind and body aided by the cautious use

of aconite or veratrum viride; the diet must be light and concentrated, the bowels maintained in an open state, and suffering allayed by anodynes.

When, in spite of medical treatment, the progress of the tumor is not arrested, the common carotid artery, or that vessel and the subclavian artery, may be ligated. That a reasonable hope of prolonging, and even of saving, the life of the patient, may be anticipated from these procedures, is satisfactorily demonstrated by a number of cases, which are placed before the reader in the following tables compiled by Dr. S. W. Gross.

In 11 cases the carotid has been tied for aneurism of the aorta alone, with a result of 8 recoveries and 3 deaths. The symptoms were ameliorated in every instance; life was prolonged in four cases, respectively, for four, four, four, and five months; one patient was still living at the expiration of half a year in good health, with the tumor diminished in volume and much firmer than before the operation; and the patient of Mr. Holmes was alive, and supporting herself as a nursery maid, nearly five years after the ligation. There was still considerable pulsation and thrill, and a harsh bruit in the diminished tumor. In the case of Heath the relief was marked; but the man died at the expiration of four years and seven months from rupture of the sac externally. In seven examples the left carotid was tied, and the right in four. The former were all successful, while three of the latter died.

Cases of Aneurism of the Aorta treated by Ligation of Carotid Artery.

No.	Operator.	Date.	Sex.	Age.	Result.	Remarks.
1	Montgomery	1829	M.	40	Recovered	Died in 4 months from extension of inflammation to tumor.
2	Rigen	1829	...	...	Recovered	Died in 4 months from asphyxia.
3	Tillanus	......	M.	...	Recovered	Died suddenly in 5 months.
4	O'Shaugnessy	1842	M.	42	Died	Died 10th day from rupture of sac. Galvanopuncture also employed.
5	Knowles	1867	M.	42	Died	Died on 35th day from apoplexy.
6	Heath	1872	...	...	Recovered	Died in 4 years and 7 months from rupture of sac.
7	Holmes	1875	F.	21	Recovered	In good health at end of 4 years and 10 months.
8	Annandale	1875	M.	62	Recovered	Alive at end of 6 months. Tumor smaller and firmer.
9	Bryant	1877	M.	56	Died	Died on 10th day from pyemia.
10	Barwell	1877	M.	56	Recovered	Died in 4 months from disease of kidneys and liver.
11	Ashhurst	1878	M.	...	Recovered	Died on 45th day from suffocation.

In 6 cases the carotid has been tied for aneurism involving both the aorta and the innominate artery, with a result of 5 deaths and 1 recovery. The right carotid was ligated 4 times, with 4 deaths, and the left carotid was ligated in 2 cases with 1 death. The symptoms as a rule, were improved, and the sac of the aneurism was occupied by limited clots.

Cases of Aneurism of the Aorta and Innominate Artery treated by Ligation of Carotid Artery.

No.	Operator.	Date.	Sex.	Age.	Result.	Remarks.
1	Key	1830	F.	61	Died	Died in a few hours from cerebral anæmia.
2	Campbell	1845	M.	48	Died	Died on 19th day from suffocation.
3	Pirogoff	1864	M.	...	Recovered	In two months and a half tumor smaller and pulsation weaker.
4	Pirogoff	1864	F.	...	Died	Died in 3 weeks from softening of brain.
5	Hutchinson	1866	M.	48	Died	Died in 41 days from suffocation.
6	Hewson	1867	M.	51	Died	Died on 10th day from suffocation.

The carotid and subclavian arteries have been tied for aneurism of the aorta alone in 9 cases, 7 of which recovered from the operation, and 2 died. Two patients were still living with marked relief at the expiration, respectively, of ten weeks and eight months; and life was prolonged in three for thirteen months, fifteen months, and four years and seventeen days. In one-half of the cases the tumor was supposed to be innominatal; but its true nature was disclosed after death. In the case of Hobart, the first portion of the subclavian artery was tied; in the remainder the ligature was applied to its third division.

In the case of Spier, the carotid artery was occluded by constriction with the instrument depicted at page 667, and the subclavian was tied forty-eight hours subsequently. In all of the other examples both vessels were ligated simultaneously. Dr. A. B. Mott, of New York, in 1876, ligated the subclavian of a man, forty years of age, in whom the carotid had been tied one year previously for supposed aneurism of the innominate. On death from phthisis at the expiration of three years, the ascending and transverse portions of the arch of the aorta were merely dilated, and did not contain laminated clots.

Cases of Aneurism of the Aorta treated by Ligation of the Carotid and Subclavian Arteries.

No.	Operator.	Date.	Sex	Age.	Result.	Remarks.
1	Hobart	1839	F.	25	Died	Death on 16th day from hemorrhage from carotid. First portion of subclavian tied.
2	Heath	1865	F.	30	Recovered	Death in 4 years from rupture of sac externally.
3	Maunder	1867	M.	37	Died	Death on 5th day from extension of clot to heart.
4	Sands	1868	F.	43	Recovered	Death in 13 months from asphyxia.
5	Spier	1874	M	31	Recovered	Death on the 34th day from rupture of sac externally.
6	Maury	1874	M.	45	Recovered	Death in 2 months from rupture of sac externally.
7	Barwell	1879	M.	36	Recovered	Death in 15 months from dissipation and exhaustion.
	Ledford	1880	M.	42	Recovered	Alive at expiration of 8 months.
9	Wyeth	1880	F.	42	Recovered	Alive at expiration of 10 weeks.

The carotid and subclavian arteries have been tied for aneurism involving both the aorta and innominate artery in 6 cases, with a result of 4 recoveries and 2 deaths from the operation. The deligation was simultaneous in all except the case of Bickersteth, in which there was an interval of forty-eight days. In one instance life was prolonged for three months, and in another for nineteen months. In 1868 Hodges, of Boston, tied both vessels for a supposed true aneurism of the aorta and innominate; but, on death on the eleventh day from exhaustion, the latter vessels were found to be merely dilated. In the majority of the cases, the sac was almost entirely filled with laminated clots.

Cases of Aneurism of the Aorta and Innominate treated by Ligation of the Carotid and Subclavian Arteries.

No.	Operator.	Date.	Sex.	Age.	Result.	Remarks.
1	Bickersteth	1864	M.	35	Recovered	Death in 3 months from progress of the disease. Vessels tied at interval of 48 days.
2	Barwell	1877	F.	37	Recovered	Death in 19 months from bronchitis; sac filled with fine clot.
3	Barwell	1877	M.	45	Recovered	Death in 3 months and 10 days from bronchopneumonia. Sac nearly filled with laminated clot.
4	Barwell	1877	M.	48	Died	Death in 30 hours from asphyxia.
5	Ransohoff	1879	M.	48	Died	Death on 7th day from asphyxia.
6	Palmer	1880	F.	50	Recovered	Death on 125th day from hemorrhage.

Of the 32 cases contained in the tables, 20 recovered, and 12 died. The best results were obtained from ligation of one or both vessels for aneurism of the aorta alone. The mortality after tying the carotid artery was 27.27 per cent., while it was only 22.22 per cent. after deligation of the carotid and subclavian arteries; but the former operation was the more favorable in regard to the extension of life. In the majority of all the cases the tumor was diminished in size, and the distressing symptoms were relieved, while life was prolonged in nearly one-half for several months. In two cases, the fatal result was retarded for four years, and one patient was still living at the expiration of nearly five years.

These facts are of sufficient importance, in my opinion, to warrant the surgeon, after the failure of general measures, in following the suggestions of Mr. Heath, to ligate the left carotid for aneurisms involving the left side of the aorta, and to practise simultaneous deligation of the right carotid and subclavian arteries for aneurisms involving the right side of the aortic arch, or of the aorta and the innominate artery.

In a case of tubular aneurism of the innominate and arch of the aorta, Blackman tied the subclavian artery; but death occurred on the eighth day, from hemorrhage caused by the patient jumping out of bed.

The electrolytic treatment of aortic aneurism, first practised by Ciniselli, is particularly adapted to cases in which the tumor is situated within the chest, and communicates with the aorta by a narrow opening. The insulated needles, two or three in number, should be attached to the positive pole of a battery of large electro-motor force, and the action · should be maintained for a period varying from five to thirty minutes, and be repeated as occasion may require. The results of galvano-puncture have thus far been rather encouraging, since of 27 cases collected by Dr. John Duncan, of Edinburgh, 5 were cured, 10 were relieved, 9 were unrelieved, and 3 died.

Fig. 338.

Aneurism of the Arch of the Aorta nearly filled with laminated Clots.

The insertion of iron wire, horsehair, and other foreign materials, with the view of inducing coagulation of the contents of the sac, holds out no prospect whatever for permanent relief, and has been attended with an almost invariably fatal result.

Laryngotomy has been advised when suffocation is threatened by spasm of the glottis from irritation of the recurrent laryngeal nerve, as a means of palliating suffering and prolonging life; but, owing to the difficulty of the diagnosis, it is not probable that many cases will be subjected to such an ordeal. When the constriction depends upon pressure of the aneurism upon the windpipe, such an operation would, of course, be useless.

The annexed sketch, fig. 338, from Jones and Sieveking, represents an aneurism of the arch of the aorta, the cavity of which is nearly filled with laminated clots. Nature had evidently made an effort, almost a successful one, at spontaneous cure.

ANEURISM OF THE INNOMINATE ARTERY.

The relative frequency of aneurism of the innominate artery does not admit of any definite statement, owing to the great discrepancy in our statistics. Thus, in 179 cases of spontaneous aneurism, excluding those of the aorta, analyzed by Listranc, the innominate is mentioned only four times, while the carotid is mentioned seventeen times, and the subclavian sixteen. In Mr. Crisp's table of 551 cases, embracing 234 of aneurism of the aorta, the innominate was affected in 20, the carotid in 25, and the subclavian in 23. The disease, as in the other arteries, is much more common in men than in women, and in the laboring than in the higher classes of persons. The greatest number of cases occur between the thirty-fifth and fifty-fifth years. It may exist by itself, or be associated with aneurism of the arch of the aorta, the carotid, or subclavian. The extent of involvement varies from the slightest increase of the normal size to an enormous tumor, either tubular, fusiform, or sacculated in its character. Whether every portion of the vessel is equally liable to be affected is uncertain, but observation shows that the disease is sometimes situated so low down as to become identified with the arch of the aorta, while at other times it is so high up as to extend into the carotid and subclavian. Occasionally it is limited to the middle of the vessel, each extremity retaining its healthy appearance.

Symptoms.—Aneurism of the innominate artery usually begins as a small projection at the right sterno-clavicular articulation, between the trachea and the inner edge of the sterno-mastoid muscle, immediately above the inner third of the clavicle. In some cases the patient is conscious of the moment when the accident takes place, from a feeling as if something had given way while he was shaken by a violent paroxysm of coughing or engaged in lifting a heavy weight. The tumor is at first generally very diminutive, probably not exceeding the size of a little almond, of a rounded or ovoidal shape, distinctly circumscribed, and slightly movable on pressing the finger firmly down into the hollow at the top of the sternum. It is not long, however, before it increases in volume; commonly, in fact, it grows rapidly, soon attaining a large bulk, extending upwards into the neck, and laterally towards each side, but especially towards the right, where there is

least resistance. As it progresses, it gradually pushes forwards the sterno-mastoid muscle, and even the sterno-clavicular articulation, forming thus a large prominence, beating and throbbing violently beneath the skin. Now and then, upon escaping from the chest, the tumor ascends high up into the neck, perhaps nearly on a level with the larynx, and it is then not uncommon for it to present a constricted, hourglass-like appearance, as if a cord had been drawn tightly across its middle.

Effects on Neighboring Structures.—The effects which the tumor exerts upon the neighboring parts, fig. 339, are chiefly of a mechanical character, and must be considered with reference, first, to the vessels of the superior extremity, neck, and head; secondly, the trachea and œsophagus; thirdly, the aorta, heart, and vena cava; fourthly, the nerves of the neck and chest; and, lastly, the sternum, clavicle, and ribs.

The pressure of the tumor upon the subclavian has the effect of weakening the force of the circulation at the wrist, and in some cases even of entirely sup-

Fig. 339.

Aneurism of the Innominate Artery, proving fatal by bursting into the Trachea.

pressing it. Occasionally the pulse is extremely irregular, beating not only more feebly than that in the opposite limb, but ceasing to act synchronously with it, the blood hitching and halting, as it were, on its way to the hand. Any tumor may, of course, produce such an effect, and there is, therefore, nothing characteristic in it. In aneurism of the aorta, the signs of enfeebled circulation are, as a general rule, most strongly marked on the left side, as the tumor, from its proximity to the left subclavian, exerts a more direct and controlling influence upon that vessel than it does upon the right subclavian. The pulsation of the carotid and its branches is sometimes diminished both in innominatal and aortic aneurism, but more frequently in the former than in the latter. It is, however, a rare occurrence in either case, and, therefore, of no diagnostic value.

Compression of the veins at the root of the neck, as the innominate, jugular, and subclavian, but especially the first, by impeding the return of blood to the heart, occasionally causes œdema of the right side of the head, face, and eyelids, and of the corresponding limb, extending as low down as the hand and fingers. The occurrence, however, is uncommon, and it is probable that it may be due, in part, to obstruction of the right lymphatic duct, as it lies just behind the tumor.

As the aneurism enlarges, it necessarily encroaches more and more upon the trachea, pushing it over towards the left side, and also somewhat backwards. When the displacement is considerable, the patient breathes with difficulty, and is occasionally unable to lie down, owing to the mechanical obstruction to the introduction of the air. Should the tumor be situated unusually low, or be of extraordinary size, it may compress and flatten the right bronchial tube. Dyspnœa from both of these causes, however, is less frequent in aneurism of the innominate artery than in aneurism of the arch of the aorta, as, in the latter disease, the tumor enlarges most in a backward direction, its progress forwards being interfered with by the sternum and clavicle. Displacement of the œsophagus is sometimes present in both affections, but not so often as has generally been supposed. When existing in a high degree, it may seriously embarrass the function of deglutition, especially the passage of solids.

When the aneurism occupies the inferior portion of the artery, and especially when it extends downwards into the chest, it follows, as a necessary consequence, that it must press upon the aorta, heart, and vena cava, pushing them out of their natural position, and perhaps seriously diminishing their capacity. The particular effect which such compression must exert cannot always be diagnosticated, but it is reasonable to conclude that it will manifest itself in disordered circulation, especially in tumultuous and confused cardiac action, enfeebled pulse, and more or less dyspnœa. An aortic aneurism will, of course, be more likely to produce such phenomena than an innominatal.

Pressure of the tumor upon the nerves of the neck and chest induces not only pain and cough, but gives rise, in many cases, to severe dyspnœa and dysphagia, the two latter symptoms being not always, by any means, exclusively dependent upon the displacement
and flattening of the trachea and œsophagus. On the contrary, they sometimes exist in a very marked and even in an aggravated degree when there is apparently very little, if any, compression of these tubes. We must, therefore, look for some other explanation of these phenomena, and the most plausible one that suggests itself is that they are due to the compression of the pneumogastric, phrenic, laryngeal, and sympathetic nerves, which are thus disqualified for transmitting, in a regular and harmonious manner, their peculiar influence to the organs to which they are distributed, and in which they naturally play so important a part.

The dyspnœa, although not a constant symptom, is often enough present to render it one of great importance. It varies in degree from the slightest change in the natural respiration to the most frightful embarrassment, in which the patient is almost suffocated, and unable to maintain the recumbent posture. It is, of course, most severe and distressing when the tumor has acquired an unusual bulk, compressing the pneumogastric and other nerves, and so interrupting their healthy action. It may be constant, or paroxysmal, coming on at irregular intervals, lasting for some time, and then gradually receding, although, perhaps, at no time wholly absent.

The dysphagia is also variable in degree, being at one time very slight, and at another so severe as almost to prevent the patient from swallowing any kind of food, whether solid or fluid. In the more aggravated cases the difficulty is constant, and the patient finally dies from starvation. It is a remarkable fact that in almost every instance of dysphagia this symptom is preceded by dyspnœa.

The pain which accompanies the disease is most severe in the right side, in the situation of the tumor, from which it radiates in various directions, particularly along the right side of the neck and head, and the corresponding side of the chest, shoulder, and arm. Occasionally, although rarely, it is also keenly felt on the opposite side. It is generally of a dull, aching, or gnawing character, and is often so excessive as to require the use of large doses of anodynes for its temporary relief.

Cough is occasionally present, probably in one case out of every three or four, but it is less common than in aortic aneurism, and is a symptom of no special value. It is evidently produced by the pressure of the tumor upon the laryngeal nerves, and varies much in frequency and severity in different cases and under different circumstances. From the same cause there is sometimes an altered state of the voice.

When the tumor is very large, and extends outwards and downwards, so as to compress the cervical and brachial plexus of nerves, it may induce partial paralysis, as well as, in some cases, partial loss of sensation, in the upper extremity. Such an occurrence, however, is extremely rare, as the sac seldom attains so much magnitude.

Permanent contraction of the pupil on the affected side is occasionally noticed; it often comes on early in the disease, and is evidently due to the pressure which the tumor exerts upon the sympathetic nerve.

There is sometimes marked alteration in the respiratory sounds; more frequently, however, in aortic than in innominatal aneurism. The breathing, when affected, is disposed to be stridulous, or wheezing, and this is sometimes the case even when the patient is in the erect posture. The respiratory murmur is seldom affected in innominatal aneurism, obviously because the tumor encroaches but little, if any, upon the lungs: it is only when it extends deep down into the thorax that it is likely to produce such an effect, and then, but not otherwise, there will, also, of necessity, be dulness on percussion of the chest, over the site of the disease. Both these phenomena are more frequent in aortic aneurism, because the tumor in that disease always encroaches more upon the lungs than in the former case.

Finally, the pressure of the tumor occasionally induces serious disease in the neighboring bones, as the sternum, clavicle, and first rib, the contiguous portions of which are liable, in the first instance, to be displaced, then to become carious, and ultimately to be wholly absorbed. In some cases there is complete dislocation of the sterno-clavicular joint.

Diagnosis.—After what has just been said, it will easily be understood that the diagnosis of aneurism of the innominate artery must often be extremely difficult, its situation at the root of the neck rendering it liable to be confounded with aneurism of the arch of the aorta, the carotid, and subclavian. Then, again, certain tumors—fatty, fibrous, glandular, and cystic—sometimes form here, and receiving an impulse from the innominate, or even from the aorta itself, may thus simulate the affection in question. I have occasionally encountered great difficulty in determining the diagnosis of disease in the inferior cervical region in consequence of abnormal pulsation either of this vessel or of the aorta, apparently dependent upon an anemic condition of the system, or neuralgia of the arteries,

and so violent as to communicate a severe shock at every contraction of the left ventricle of the heart to the innominate and its two branches, the carotid and subclavian. The embarrassment, in these cases, is materially increased if, superadded to the pulsation, there is an unusual quantity of fat, or some solid growth, and the sharp thrill so common in the arteries of anemic subjects.

This difficulty was strikingly felt in a case, which occurred a few years ago in the practice of Dr. Sands, of New York, in a middle-aged woman, a patient in the Bellevue Hospital, who had a soft, pulsating tumor at the root of the neck. It was situated behind the right sterno-clavicular articulation, and extended upward two inches above the clavicle, being partly covered by the sterno-mastoid muscle. The patient was carefully examined by a number of the most eminent surgeons and physicians, who all concurred in the diagnosis of innominatal aneurism, except one, who thought that the aorta, as well as the innominate, was dilated, his opinion being founded on the presence of a circumscribed spot in the right suprascapular space, which was dull on percussion, and which transmitted, very distinctly, the aneurismal murmur. On the 16th of July, 1868, Dr. Sands, to whom I am indebted for an account of the case, performed the distal operation, by tying simultaneously the carotid and subclavian arteries. The ligature of the carotid was applied immediately above the omohyoid muscle; that of the subclavian was external to the scalene. The patient recovered from the operation, and the tumor diminished in size, the dyspnœa and other pressure symptoms being at the same time relieved, so that hopes were entertained of a permanent cure. Gradually, however, the swelling again increased, and the patient sank from dyspnœa, thirteen months after the operation. At the dissection, a sacculated aneurism was discovered, about the size of a large pear, arising by a narrow orifice from the aorta, directly in front of the origin of the innominate artery. The latter vessel was healthy, and was behind the aneurismal sac, nearly four inches from the external surface.

On the whole, the most reliable diagnostic signs of aneurism of the innominate are, first, the situation of the tumor at the right sterno-clavicular joint, immediately above the inner third of the clavicle, where it forms a distinct, well-marked prominence; secondly, stoppage of aneurismal beat, thrill, and bellows sound by pressure upon the carotid and subclavian; and, thirdly, unnatural weakness of the pulse at the right wrist, with pain and œdema on the corresponding side of the neck, shoulder, and arm. In aortic aneurism, the tumor seldom projects sensibly above the sternum; certainly not before it has attained considerable bulk, and then it is situated rather in the middle line than on the right side; the arterial pulse, if affected at all, is weakest on the left side, and there also the œdema and pain are most conspicuous; the dyspnœa, dysphagia, cough, stridulous respiration, and change of voice are more frequent than in the innominatal disease; and compression of the carotid and subclavian produces no diminution in the sounds of the tumor.

The prognosis of brachio-cephalic aneurism is extremely unfavorable. The disease, it is true, may last for a considerable time, but this is very unusual; in general, it progresses very rapidly, and soon reaches a fatal crisis, the tumor either opening externally, into the trachea, or into the chest, or else, as is commonly the case, wearing out the patient by constitutional irritation, asphyxia, or inanition. No instance of spontaneous cure has ever been known to occur in this disease.

Treatment.—The treatment of aneurism of the innominate has hitherto been most unsatisfactory. Owing to the short and stunted character of this vessel, and the close proximity of the aneurism to the arch of the aorta, deligation on the Hunterian principle is, of course, altogether impracticable, and hence the only resource is either to treat the disease upon the plan of Valsalva, or to tie the carotid and subclavian at the distal side of the sac, according to the method originally suggested by Brasdor. The treatment of the Italian surgeon holds out but little encouragement, the disease generally going on from bad to worse until it reaches its fatal crisis, despite the most abstemious course of dieting, rest in the recumbent posture, the use of the lancet, and the exhibition of digitalis, opium, and acetate of lead, to promote the formation of clots. With the exception of Mr. Luke's case, there is hardly an instance upon record in which it was followed by any ultimate benefit. Squeezing the tumor, if practicable, would certainly not be justifiable, as the detached clots might, and probably would, fall into the aorta, and thus cause serious, if not fatal, results on the spot, from mechanical obstruction to the circulation. The operation of Brasdor has been performed in a number of cases, which will be placed before the reader in tabular form.

In 3 cases the carotid and subclavian have been tied successively, as recommended by Mr. Fearn, of Derby, England, with 3 deaths.

Cases of Aneurism of the Innominate treated by Consecutive Ligation of the Carotid and Subclavian Arteries.

No.	Operator.	Sex.	Age.	Carotid ligature.	Subclavian ligature.	Remarks.
1	Fearn	F.	28	August 30, 1836	August 2, 1838	Died from pleurisy nearly four months after second operation. The aneurismal sac was found filled with dense, organized coagula, except a channel the size of the artery for the passage of blood.
2	Wickham	M.	55	Sept. 25, 1839	Dec. 3, 1839	The aneurism increased, and burst with mortal hemorrhage 63 days after the second operation.
3	Malgaigne	M.	...	March, 1845	October 17, 1845	Four days after the operation the tumor increased rapidly in size, the tumefaction became diffused, and the patient died on the 7th Nov. At the autopsy, the sac could not be dissected; it was confounded with the muscles; in other words, the aneurism was diffused.

In 14 cases the carotid and subclavian have been tied simultaneously, with a result of 7 recoveries and 7 deaths from the operation. Two patients were still living with alleviation of the symptoms and decided diminution in the size of the tumor, at the expiration respectively, of three and a half and ten months; and life was extended in one for twenty-two months, and in another for three years and four months, when, on death from phthisis, the sac in both cases was found to be almost filled with firm, laminated clot.

Cases of Aneurism of the Innominate treated by simultaneous Ligation of the Carotid and Subclavian Arteries.

No.	Operator.	Date.	Sex.	Age.	Result.	Remarks.
1	Rossi	1843	...	...	Died	Death on 6th day from cerebral anemia.
2	Lane	1871	F.	40	Recovered	Death in 3 months from rupture of sac.
3	Holmes	1871	M.	50	Recovered	Death on 55th day from rupture of sac.
4	McCarthy	1872	M.	...	Died	Death on 15th day from hemorrhage from subclavian.
5	Ensor	1874	M.	50	Died	Death on 65th day from hemorrhage from sac through carotid wound.
6	Eliot	1876	M.	41	Died	Death on 26th day from repeated hemorrhage from ruptured sac.
7	Weir	1876	M.	45	Died	Death on 15th day. Aneurism had burst into trachea.
8	King	1876	M.	37	Recovered	Death on the 111th day from rupture of sac.
9	Little	1877	M.	46	Recovered	Death from phthisis in 3 years and 4 months.
10	Stimson	1879	M.	34	Recovered	Patient died of phthisis at expiration of twenty-two months.
11	Barwell	1879	F.	27	Recovered	Patient alive at expiration of ten months.
12	Durham	......	...	...	Died	Death on 6th day from shock.
13	Pollock	1881	M.	37	Died	Death on 10th day from dyspnœa.
14	Browne	1881	M.	32	Recovered	Pulsation diminished, and bruit and pain had disappeared at expiration of three months and a half.

In 4 cases the subclavian alone has been tied, with a result of 3 recoveries and 1 death from the procedure. In the successful cases there was marked improvement in the symptoms, and life was prolonged in one instance for three years.

Cases of Aneurism of the Innominate treated by Ligation of the Subclavian Artery.

16	Newton	......	M.	...	Died	Death on 12th day from effusion into the chest.
17	Pirogoff	......	M.	...	Recovered	Patient alive at expiration of two months and a half.
18	Nussbaum	......	...	...	Died	Death from rupture of sac.
19	Nussbaum	......	...	...	Died	Death from rupture of sac.
20	Bryant	1880	M.	40	Died	Death on 19th day from dyspnœa.

A careful examination of the above cases affords the following conclusions concerning the deligation of the primitive carotid for the cure of innominatal aneurism:—

1. It reduces the volume of the tumor. Thus, in the case of Mr. Evans, of Derby, in 1828, although the aneurism was as large as a walnut, it entirely disappeared in a little upwards of a month. In Dr. Mott's second case, in 1829, it was of the size of a pigeon's egg, and disappeared in twenty-six days.

2. The operation leads to fibrinization of the contents of the sac. These changes, which are due, not to arteritis, but to remora of the blood, were well displayed in the cases reported by Mr. Morrison, of Buenos Ayres, in 1832, Sir William Fergusson, in 1841, and Dr. Wright, of Montreal, in 1855. In the first, the innominate artery was larger than natural; and in all, the tumor was nearly filled with firm clots.

3. The operation is attended with certain risks; but the deaths were due not, apparently, to any agency of the aneurism, but to the danger which naturally succeeds to the ligation of the common carotid, for whatever purpose. Thus, in the instances of Mott, Vilardebo, and Broadbent, death resulted from secondary hemorrhage. In the case of Fergusson, the patient died of pneumonia; and in the case of Porta the fatal result was due to erysipelas. In the instances of Hutton, Scott, and Nussbaum, the cause of death was rupture of the sac, also a very common effect of the operation for carotid aneurism, whether the ligature be placed above or below the tumor. In two instances, those of Neumeister, and Dohlhoff, the patients died of the effects of ligation of the artery upon the brain; and in that of Wright, death was due to abscess of the brain.

4. The operation has not been productive of a long after-life, chiefly, perhaps, because the cases demanding it were nearly all inherently hopeless, from being associated with organic disease of the aorta, or of this vessel and of the heart. Distinct evidence of this fact existed in at least seven of the cases; in the rest no accurate examination was made. The influence of such complications is shown by the results which followed Brasdor's operation in aneurism of the root of the carotid unmixed with any other lesion. Of eight cases of this kind, six completely recovered, and two died.

5. The operation lengthens life if perilled by rupture of the sac, or pressure on the windpipe. In fact here is its great triumph. In the case of Professor Wright, although the man was in imminent danger before the operation, yet he survived it eighty-eight days. The mean duration of life after deligation of the carotid, under ordinary circumstances, is about four months and a half.

6. The operation has occasionally failed to effect any local improvement. This result

followed in several of the cases, in consequence of a want of fibrinization of the contents of the sac.

The facts above stated, deduced mainly from the paper of Professor Wright, in the Montreal Journal of Medicine, clearly point, as that gentleman justly remarks, to a division of cases in regard to the applicability of the operation. 1. The most suitable cases are those of uncomplicated innominatal aneurism, being akin to the pure carotid form, the sac, which is confined to the part of the vessel near the bifurcation, springing from the left segment of the artery, and not coexisting with degeneration of its tunics or cardiac disease. 2. Those imperatively requiring it are such as entail imminent danger from external rupture of the tumor or from other causes. 3. The most favorable cases are aneurisms proceeding from the left segment of the artery, because then the introduction of blood into the sac is most effectively impeded, as it is derived from the current destined for the vessel which is tied, whereas, when the aneurism is dextro-lateral, the same benefit cannot be afforded, as the supply is furnished by the subclavian. Next to this situation, the most preferable, anatomically, would be the origin of the tumor from the anterior circumference of the vessel. 4. The less advantageous cases are those in which the external tumor extends towards the middle of the clavicle, for this occurrence denotes such an engagement of the subclavian as must effectually counteract any benefit derivable from ligature of the carotid. When the swelling is equal on each side of the innominate, or symmetrical, then the only hope of a certain stasis of blood would be afforded by tying both branches. 5. The cases contraindicating the operation are those having complications with aortic aneurism, or serious disease of the heart, unless excepted by extreme urgency.

ANEURISM OF THE COMMON CAROTID ARTERY.

Spontaneous aneurism of this vessel is less frequent than is generally supposed, owing, doubtless, to the fact that it is so seldom the seat of the fatty and calcareous degenerations. Of 551 cases of aneurism of different parts of the body, embracing 234 of the aorta, the carotid is stated by Mr. Crisp to have been affected in 25, or in the ratio of 1 to 22. Of 179 cases analyzed by Lisfranc, 17 refer to the carotid, 16 to the subclavian, 14 to the axillary, 26 to the femoral, and 59 to the popliteal. The disease in 47 involved the aorta.

The affection is much more frequent in men than in women, in the proportion of about three to one. Thus, in the statistics of 712 cases out of 789, compiled by Dr. Wyeth, in which the sex is stated, 538 were males, and 174 were females.

Age exerts a marked influence upon the production of the disease. The period of life from the twentieth to the fortieth year furnishes the greatest number of cases. It is occasionally witnessed at a very early age. Wyeth's tables comprise 16 cases under twelve months, and 22 cases under ten years. Although the fact is not stated, it is evident that most of these cases must have been of traumatic origin or of an anastomotic nature. The disease occurs with nearly equal frequency on both sides, and, in fact, sometimes exists simultaneously in both arteries. No occupation is exempt from it.

The site of carotid aneurism is variable. Sometimes the tumor is situated very low down in the neck, close to the origin of the vessel; on the other hand, it may be high up, near its bifurcation. In the great majority of cases, however, it will be found to be between these two points, or near the middle of the artery; usually rather above than below.

Symptoms.—The tumor, when first observed, is generally quite small, perhaps not exceeding the size of a filbert, and of an irregularly globular, rounded, or ovoidal shape. The patient, upon being questioned as to the history of the case, usually expresses his ignorance as to the time of its occurrence, though occasionally he is rendered conscious of it by a peculiar stabbing sensation in the neck, or a feeling as if something had suddenly snapped asunder. Commonly the surgeon is not consulted until the tumor has made considerable progress, and acquired the volume of a hen's egg, or of a small orange, the patient, perhaps, having all along supposed that the swelling was merely an enlargement of some of the cervical glands. A careful inspection, however, promptly reveals its true character, its pulsation, thrill, and bellows sound affording unmistakable evidence of its close and intimate arterial connection. Pressure upon the cardiac side of the aneurism, by stopping its circulation, arrests these symptoms, and causes a sensible diminution of the size and consistence of the tumor, while pressure upon its distal side produces an opposite result. As long as it is small, the tumor may readily be moved

about, and even raised out of its bed, especially if it be grasped with the thumb and forefinger during the relaxed condition of the sterno-mastoid muscle; as it augments in volume it becomes more fixed in its position, and is eventually rendered almost, if not entirely, stationary.

The symptoms of carotid aneurism are mainly of a mechanical character, being such as arise from the pressure of the tumor upon the neighboring parts; hence, their gravity is generally in proportion to the volume of the morbid growth. In the earlier stages of the disease, there is either no functional disturbance whatever, or it is so insignificant as not to attract any special attention; by and by, however, as it progresses, the tumor necessarily encroaches more and more upon the delicate and important structures of the neck, thus occasioning congestion of the brain by retarding the return of the blood in the jugular vein, numbness, pain, and cough, by compressing the cervical, pneumogastric, and phrenic nerves, and difficulty of respiration, and, perhaps, even of deglutition, by bearing against the trachea and œsophagus. The surface of the swelling, at first perfectly natural, becomes gradually indurated and inflamed, the subcutaneous veins are unusually conspicuous, and the neck is stiff, distorted, and almost immovable. The greatest enlargement of the tumor is generally in the direction of the middle plane, as the resistance is much less there than externally, under the edge of the sterno-cleido-mastoid muscle.

Diagnosis.—Notwithstanding that the symptoms of carotid aneurism are usually well marked, cases, nevertheless, occur in which they are so obscure as to render it extremely difficult to determine the diagnosis, even after the most careful and patient investigation. The affections of the neck which are most liable to be confounded with carotid aneurism, and to render the discrimination doubtful, are diseased lymphatic glands, abscesses, cystic tumors, goitre, dilatation of the internal jugular vein, and aneurism of the innominate artery and arch of the aorta.

Enlargement of the *lymphatic glands* of the neck is most common in young subjects, before the age of twenty, whereas aneurism of the carotid is rarely met with until after thirty; moreover, it is almost peculiar to scrofulous persons, while aneurism occurs in all classes of individuals, the strumous and the non-strumous. In aneurism the tumor is generally well defined; its surface is smooth and uniform, and the swelling heaves and throbs, as if it were alive. In glandular enlargement, there is generally a chain of diseased glands, either scattered about in different parts of the neck, or stretched along the inner border of the sterno-cleido-mastoid muscle; the tumors feel hard, and may, with a little care, be easily separated, not only from each other, but from the carotid artery, so as to get entirely beyond the reach of its pulsation.

An aneurism of the carotid artery has sometimes been mistaken for an *abscess;* the tumor has been punctured, and the patient has speedily perished of hemorrhage. Such an error, of course, implies great carelessness, and could hardly happen at the present day, when our means of diagnosis are so much more perfect than they were formerly. The discrimination must be determined on general principles. If there is an abscess, the history of the case, conjoined with the unnatural heat and redness of the part, the rapid progress of the swelling, the febrile disturbance, and the absence of the characteristic pulsation, thrill, and bellows sound, will be sufficient to distinguish it from aneurism of the carotid artery.

Cystic tumors, usually containing a serous or sero-sanguinolent fluid, are liable to form at the front and sides of the neck, most generally in connection with the thyroid gland, but sometimes independently of it, in the connective tissue beneath the muscles. They may usually be readily distinguished by their slow growth and fluctuating feel, the absence of pain and pulsation, and, when they are attached to the thyroid gland, by their obeying the movements of the larynx in the act of deglutition. If, after a careful examination of their history, any doubt exists as to their real nature, the only resource will be the cautious introduction of the exploring needle.

Goitre is liable to be mistaken for carotid aneurism only when it spreads laterally over the neck, so as to overlap the carotid, and receive its pulsation. It is certainly not possible to commit any error of diagnosis in the more ordinary and simple forms of the disease. Confusion is most apt to arise when aneurism and goitre coexist, or when, as occasionally happens, the latter disease is developed uncommonly rapidly, and is attended with considerable local distress. Ordinarily, goitre forms in early life, at a period when aneurism is extremely infrequent; it is generally tardy in its progress, several years elapsing before it attains any material bulk, and it is subject to occasional interruptions, and even total suspension, whereas aneurism generally advances rapidly

and steadily, the symptoms proceeding from bad to worse, until it attains its crisis. Another important criterion is the fact that goitre is almost peculiar to females, whereas carotid aneurism occurs by far most frequently in men. But the most satisfactory diagnostic signs are, first, that in goitre, the tumor obeys the movements of the larynx, whereas in aneurism it remains stationary, however strong the efforts at deglutition ; secondly, that in the former the tumor may be drawn away from the vessel, raised up or pushed to one side, while in the latter the vessel follows it, forming, as it does, a part of it ; and, lastly, that in goitre the general health rarely suffers, even when the tumor is of large bulk, whereas in aneurism it is always more or less impaired, especially when it has reached such a stage as to be likely to occasion embarrassment in regard to the discrimination between the two affections.

A dilated condition of the internal *jugular vein* may simulate aneurism of the carotid artery. The deception will be the more likely to happen if the vein receive a pulsatory movement from the heart or from the carotid, as when the artery is overlapped by the vein. The venous tumor may generally be distinguished by its softness and compressibility, by its situation, which is commonly just above the sternum, and rather behind than in front of the sterno-cleido-mastoid muscle, and by the circumstance that its motion is more of an undulatory, wave-like, or tremulous character, than shock-like and vibratory, as in aneurism. Superadded to this is the fact that the venous swelling may readily be effaced by pressure applied to its distal extremity, whereas, in aneurism, the pressure, to produce any appreciable effect of this kind at all, must be applied to the cardiac extremity of the tumor, and then it will result only in a diminution, not in complete obliteration.

Finally, a carotid aneurism may be confounded with aneurism of the *innominate artery*, or of the arch of the aorta, especially if it be situated low down in the neck. When this is the case, the difficulty may be very great, if not insurmountable. The most reliable diagnostic sign with which I am acquainted, and one that will rarely fail, in such an emergency, is afforded by our ability to insinuate the point of the forefinger between the top of the sternum and the lower extremity of the aneurism, while the head is being bent powerfully forwards, so as to relax as fully as possible the sterno-mastoid muscles. If this can be done, the probability is that the tumor is connected with the carotid ; otherwise it may be inferred that it is formed by the innominate artery, or by the arch of the aorta.

Several examples have been recorded in which aneurism of the *vertebral artery* was mistaken for aneurism of the common carotid, the latter vessel having actually been tied for the relief of the disease. All the cases, about four in number, proved fatal.

Progress.—The progress of carotid aneurism, although usually rapid, is not so always. The annals of surgery contain several cases where the disease remained almost stationary for a considerable number of years ; in one as many as fourteen. A spontaneous cure sometimes occurs, but such an event must necessarily be extremely rare. The tumor, if allowed to go on unchecked, eventually, generally at a period varying from three to twelve months, destroys life either by excessive constitutional irritation, hemorrhage, gangrene, pneumonia, or asphyxia. When seized by ulceration, it may burst either externally, or it may open into the pleura, the anterior mediastinum, the trachea, or one of the bronchial tubes. Esmarch and Teale have each related a case of fatal embolic apoplexy from the detachment of fibrinous clots in an aneurism of the common carotid artery, from pressure exerted upon the tumor with a view of ascertaining its real character.

Treatment.—The treatment of carotid aneurism is generally conducted according to the Hunterian principle of ligating the supplying vessel at the cardiac side of the tumor; and, fortunately, as the disease is ordinarily situated rather high up, this may commonly be done without any very great difficulty, especially in the earlier stages of the affection, before the swelling has attained much bulk. When the tumor is of great size, or located at the inferior part of the neck, we may be compelled to adopt the method of Brasdor, and tie the carotid on the distal side of the aneurism, trusting that the blood in the tumor, no longer finding an outlet, will gradually coagulate, and so effect its obliteration. The fact is, this artery, owing to the total absence of collateral branches, is peculiarly adapted to this operation, and it is well that it should be so, seeing that, if it were otherwise, we should be obliged to resign many of the more severe cases of carotid aneurism to their fate, without any attempt whatever at surgical interference. It is obvious, from the relations of the vessels and nerves of the neck to the tumor, that compression, now so much employed in the treatment of aneurism of the lower extremity, can seldom be

brought into play here, the parts being intolerant of the requisite manipulation, to say nothing of the obstruction which it would occasion to the return of the blood in the internal jugular vein, which, being dammed up in the brain and the sinuses of the dura mater, might speedily induce apoplexy, or other serious cerebral symptoms, endangering the patient's life. When the tumor is of extraordinary bulk, rendering ligation of the carotid impracticable at any point, our only hope, faint though it be, is the success of general measures, particularly Valsalva's method; for experience has conclusively proved that no benefit is to be expected from the ligation of the innominate artery, as originally proposed and practised by Dr. Mott. The deligation of the terminal branches of the carotid might be tied with a better prospect of success, but this also would be likely to fail, owing to the numerous offsets of the external carotid, which, unless included in separate ligatures, would continue to transmit the blood from the tumor with sufficient force and activity to maintain its circulations unimpaired, and so inevitably frustrate the intentions of the operation.

When the tumor is unusually voluminous, or even of moderate size, but situated very low down, overlapping and compressing the trachea, the symptoms may be so urgent as to demand the operation of laryngotomy, to save the patient from impending asphyxia. Such an event must, however, be very uncommon.

A very interesting case of carotid aneurism has been related by Dr. Robertson, of Edinburgh, in which he performed an operation after the tumor had burst into the œsophagus. The swelling was situated so low down that he was compelled to ligate the vessel only half an inch above its origin from the innominate artery. Notwithstanding these unfavorable circumstances, the patient made an excellent recovery, the ligature coming away on the seventeenth day.

The operation of tying the carotid is ordinarily easy enough, but when the aneurism is large, or the neck very short and fat, it is one of the most difficult and trying undertakings in surgery. The principal accidents likely to attend it are the inclusion of the jugular vein and pneumogastric nerve in the ligature, and the wounding of some of the smaller vessels of the neck, which it is sometimes more difficult to find and secure than the carotid itself.

The old procedure of laying open the sac, turning out its contents, and tying both ends of the vessel, was practised by Mr. Syme, in a case of traumatic aneurism of the lower part of the left carotid, the result of a stab two months previously. A small incision being made into the tumor, the finger was passed in so as to plug the puncture, and then the point was carried about till it hit the precise spot where pressure controlled the pulsation. The sac was now freely opened, the clots sponged out, and a ligature applied to each end of the vessel. In this part of the operation great annoyance was experienced on account of the difficulty of finding the orifices of the artery, and it was not until after the division of the sterno-cleido-mastoid that the object could be attained, such was the confused condition of the inner surface of the sac. The patient, notwithstanding his apparently desperate condition, made an excellent recovery. This bold operation was successfully imitated, in 1875, by Dr. Frothingham, of Ann Arbor, in a similar case, in which he emptied the sac, and tied the artery at both ends. Such an operation, it is evident, can be performed only by a surgeon of consummate ability, with thorough anatomical knowledge, and the most perfect self-possession. In the hands of a less competent man it might instantly be fatal.

Mortality and other effects.—Of the mortality of the operation for carotid aneurism, a tolerably accurate estimate may be formed from the data now before the profession. Of 21 cases mentioned by Mr. Crisp, 10 were successful, and 11 fatal. In 5, the artery was ligated at the distal side of the tumor, and of these, 3 recovered, the other 2 being only somewhat benefited. Of the 11 fatal cases, 5 were lost by hemorrhage, 2 by inflammation of the sac and artery, and 1 by spasm of the glottis, the cause of death in the remaining 3 being doubtful. The table of Dr. Norris contains an analysis of 38 cases, in which the carotid was tied for aneurism, including 4, however, in which the disease was found, after the operation, not to have been connected with the artery. Of these cases, 22 recovered, and 16 died. The cause of death is mentioned in only 12 of the cases; in 5 it was hemorrhage, in two inflammation of the sac, in 2 apoplexy and congestion of the brain, in 1 cerebritis, in 1 spasm of the glottis, and in 1 exhaustion.

In 6 of the 38 cases, the aneurism suppurated, and either burst or was laid open; of these, 4 died and 2 recovered. In one instance the opening in the sac occurred four months, and in another nearly eight months, after the operation. In one fatal case, the tumor burst into the pharynx fifteen days after the deligation of the artery, and in

another case, which, however, recovered, it had discharged some of its contents into the mouth prior to the operation.

Return of pulsation in the tumor, after the operation, was noted in 9 of the 38 cases; in one the pulsation never ceased entirely for two months, and in another it continued for upwards of four months.

The detachment of the ligature occurred, in 13 cases, before the twentieth day; in 7, between the twentieth and thirtieth, and in 1 on the thirty-third day. The time in the remaining cases was not observed.

In seven of the cases, analyzed by Dr. Norris, there was a mistake in the diagnosis, as was proved on the dissection, for all the patients died. In four, the disease consisted of different kinds of tumors; in two, of aneurisms supposed to be abscesses; and in one of an aneurism of the vertebral artery. The examples of mistaken diagnosis include the celebrated case of Mr. Liston, of a lad, nine years of age, who had a tumor on the right side of the neck, of two months' standing, which, although seated over the carotid, was entirely free from pulsation, except along the track of that vessel. Under the conviction that it was merely an abscess, a bistoury was introduced, the removal of which was followed by a gush of arterial blood to the amount of four ounces. The bleeding being arrested by closing the wound with the twisted suture, the common carotid was tied on the following day, October 21st, close to its origin from the innominate artery. On the 3d of November, the arterial hemorrhage suddenly recurred, but was suppressed by plugging the wound with lint; it, however, again broke forth, and proved fatal on the 5th, that is, fifteen days after the operation. Although the ligature had retained its hold upon the artery, the proximal end of the vessel was found to be quite patulous, no attempt having been made at the formation of a coagulum. The probability is that, as Mr. Liston has suggested, the tumor, in this remarkable case, was originally a scrofulous abscess, a part of the wall of which was formed by the carotid; the latter, becoming ulcerated, finally gave way, and thus sent its contents into the cyst inclosing the matter.

Of 16 cases of ligature of the common carotid artery on the cardiac side of the tumor for aneurism of the common carotid alone, analyzed by Wyeth, 9 recovered and 7 died. Distal ligature of the vessel for aneurism of the root of the common carotid has been practised 8 times, with a result of 6 recoveries and 2 deaths. The case of Demmé is excluded, as the arch of the aorta was also involved. The operation was first resorted to by Wardrop, in 1826, and this patient was alive three years afterwards.

Injury to the internal jugular vein has been a cause of death in several cases of ligation of the carotid. In one in which Barovero included this vessel with the artery, the patient died on the sixty-ninth day of gastric fever. Mr. Crisp met with an instance where a surgeon tied the internal jugular vein instead of the carotid; the patient was a child, and the error was not discovered until after death. Fatal results have occurred several times from injury done to the pneumogastric nerve in ligating this artery.

Various serious cerebral and pulmonic symptoms occasionally follow the ligation of the carotid artery, and are among the principal sources of the mortality from this operation.

The effects which the operation produces upon the *brain* have been elucidated both by experiments upon the inferior animals and by observations upon the human subject, and manifest themselves in various ways and at different intervals. Their full importance, however, was not determined until after the publication of the researches of Mr. Chevers, of London, in 1845, to whom the profession is greatly indebted for the valuable light which he has thrown upon a subject which, up to that period, had been entirely overlooked. In the 789 cases analyzed by Dr. Wyeth, in which the common carotid was tied either for aneurism, wounds, or other causes, more or less severe cerebral disturbance occurred in 52. Some of these cases recovered completely, some got well of the operation, but remained afterwards in a crippled condition, and some, perhaps the majority, died, at a period varying from a few hours to several months.

There is no uniformity either in the character or in the manifestation of the cerebral symptoms. Sometimes they come on immediately, or, at all events, within a few hours, after the deligation of the vessel; while at other times, and perhaps most generally, they do not appear until the end of several days, weeks, or months. Their access is usually sudden, but occasionally so gradual and imperceptible as to keep the patient in ignorance of it until it is discovered accidentally. The most frequent symptoms are convulsions and paralysis. The former may be general, but much oftener they are partial, affecting, for example, one arm, a leg, or one side of the face; in some cases there are merely spasmodic twitches, or irregular, involuntary movements. The paralysis occasionally exists on the side of the affected artery, but in most cases it occurs on the opposite side, and

then it may pervade one-half of the body, as in hemiplegia, although generally it is more limited, being confined, perhaps, to the face, tongue, throat, fauces, eyelid, hand, arm, leg, or thigh.   Sometimes there is dimness of vision, with or without dilatation of the pupil; a feeling of drowsiness, somnolency, stupor, or coma; dizziness, vertigo, or headache; noise in the ears or partial deafness; delirium, either alone or conjoined with paralysis or convulsions; difficulty of deglutition; dyspnœa; a sense of coldness, or coldness and numbness.   Various other symptoms, mostly of an anomalous, nervous character, are often present.   Occasionally these effects rapidly disappear, but, in general, they are more or less persistent, and in some cases they remain up to the moment of the patient's death.   In some instances, inflammation of the brain, or of the brain and its envelopes, supervenes, either soon after the deligation of the vessel, or at a more or less remote period.

How are these phenomena produced?   Are they caused merely by an inadequate supply of blood to the brain, or are they due solely to a loss of equilibrium in the cerebral circulation?   To answer these questions satisfactorily is of course impossible.   It would seem probable, from the free anastomosis which exists between the branches of the internal carotid arteries, on the one hand, and between these arteries and the vertebral, on the other, that they could not be occasioned by a mere want of blood, inasmuch as these vessels are capable of furnishing the organ with an abundant supply of that material for the purpose of carrying on its healthy functions.   Nevertheless, it is not likely that unpleasant effects may and do follow the sudden withdrawal of a certain quantity of blood from the brain, resembling those produced by copious bleeding at the arm, or by a smart concussion of the brain.   In some instances, it is reasonable to conclude that they are the result of the inclusion of an important nerve; while in another class of cases, as when several weeks or months elapse before their supervention, they would seem to be the direct consequence of inflammation.   Under the latter circumstances, dissection reveals softening of the cerebral substance and effusion of serum, or of serum and lymph, in the ventricles and upon the surface of the brain.

The most constant *pulmonary* effects occasioned by the ligation of the carotid artery are cough, bronchitis, and inflammation of the pulmonary tissue.   Cough is not only a very frequent occurrence, but often one of great severity, rendering it sometimes extremely difficult to check it.   It generally comes on soon after the operation, in fits of a violent spasmodic character, in which the patient is in the deepest distress, looking and acting as if he were about to be suffocated.   Its duration is variable; sometimes lasting only a few hours, while at other times it continues, as a prominent symptom, for days together.   When very severe, it may occasion hemorrhage in the wound, by reopening some of the vessels.   Violent hiccough sometimes follows the operation, and may last for an almost indefinite period.

It is not easy to determine how this cough is induced.   From the fact that it often follows immediately upon the operation, it is not unlikely that it may arise from the inclusion in the ligature of some nervous filament, which thus sets up irritation in the mucous membrane of the air-passages, especially of the larynx and trachea, causing an effect not dissimilar from that awakened by the sudden intromission of a drop of water into the windpipe.   That the effect must be somewhat of this character would seem probable, when we reflect upon the spasmodic and uncontrollable nature of the cough which generally characterizes the attack.   At other times, the cough may be purely sympathetic; or, what is more likely, may be caused by the compression of the filaments of the sympathetic nerve, which are so abundantly distributed through the coats of the arteries, especially those about the neck and chest.   May not the pressure of the ligature upon the pneumogastric nerve occasion this distress?

The effects which the ligation of the carotid exerts upon the bronchia and lungs set in at various periods after the operation, and are denoted by the usual rational and physical signs.   On dissection, the mucous membrane of the former is found to be of a reddish color, either uniformly or in patches, greatly engorged with blood, and covered with pus, or pus and lymph.   The lungs are abnormally vascular, loaded with black blood, more or less hepatized, or solidified at one point and softened at another.   Blood and pus are sometimes contained in the anterior mediastinum; the pleura has been known to be the seat of extensive effusions; now and then there are traces of inflammation of the larynx and trachea; and occasionally, although rarely, the examination reveals the existence of pericarditis and endocarditis.   When the inflammation of the respiratory organs is at all considerable, the blood drawn during life generally evinces a buffed, if not also a cupped, appearance.

Such being the effects which are liable to follow, probably in one case out of every four or five, in the brain and lungs, in consequence of the deligation of the carotid, it is obvi-

ous that they should be carefully looked for, in order that proper measures may be adopted for their prompt and efficient removal the moment they arise. Much may be done, in most instances, by way of prevention, by a judicious preparatory course, consisting of venesection, purgatives, light diet, and repose of mind and body, which cannot fail to contribute materially to the protection both of the brain and lungs. The operation having been performed, these organs are most sedulously watched, the least indication that presents itself being met by appropriate means, and, in this way, the case safely conducted to a favorable issue. If the patient be pale and faint, alcoholic stimulants, cautiously and judiciously administered, will be of service; cough and convulsive symptoms are treated with anodynes and antispasmodics, particularly morphia; and inflammation is controlled by the lancet, leeches, blisters, purgatives, aconite, and antimonials.

The treatment of aneurism of the carotid artery by *digital compression* has not been tried upon a sufficiently extended scale, or under sufficiently varying circumstances, to enable us to form anything like a correct estimate of its value, or of the particular class of cases to which it is applicable; but the successful examples that have been reported by Kerr, Rouge, Gioppi, Vanzetti, Sheppard, Humphry, Gay, and Sir R. Dagin, are quite encouraging, and point to the propriety of further efforts in this direction. In the cases recorded by De Castro and Delore the procedure failed. The compression must, of course, be intermittent, and the best plan is to make it laterally, the thumb being placed against the anterior border of the sterno-mastoid muscle, and the next three fingers under its posterior edge, an expedient which allows the artery to be seized and controlled without injury to the pneumogastric nerve. In Rouge's case, in which this practice was successfully pursued, the compression was continued for seventeen days, on an average of seven to eight hours each.

The heart's action should be controlled during the treatment by venesection, opium, and veratrum viride. The exhibition of acetate of lead and ergot might be of service in promoting the formation of coagula. As little pressure as possible should be made upon the internal jugular vein, otherwise the functions of the brain might be seriously disturbed. The chief objection, I conceive, to digital compression in this situation, is the danger of embolism. The sudden impaction of a clot in the internal carotid artery or in one of its principal branches might cause instantaneous death.

Aneurismal Varix.—This affection is uncommon. It is generally caused by external injury, as a puncture made by a knife, dirk, shot, or piece of glass, establishing a communication between the carotid artery and jugular vein, so as to admit of a ready interchange of their respective contents. Instances have been published in which the affection was occasioned by ulceration. The symptoms present nothing peculiar. In the few cases of this variety of aneurism that have been recorded by different observers, as Larrey, Marx, Williamson, and Rigaud, life did not seem to have been at all abridged by the disease. Operative interference would, in fact, in any event, be unjustifiable, as it would be fraught with great danger. Of varicose aneurism, properly so called, of these vessels, no instance has, I believe, ever been reported.

ANEURISM OF THE EXTERNAL CAROTID AND ITS BRANCHES.

Spontaneous aneurism of the external carotid is perhaps still more uncommon than of the internal carotid; its history, consequently is involved in obscurity. The situation of

Fig. 340.
Traumatic Aneurism of External Carotid.

the tumor just below the angle of the jaw, its throbbing, pulsatile character, and its gradually increasing volume, would serve to distinguish it from ordinary growths in this portion of the cervical region. In an aneurism of this artery, digital compression would be worthy of trial; should this fail, the proper remedy would, of course, be ligation of the common carotid.

False aneurism of the external carotid is rarely met with, the only cases of which I have any knowledge being those of consecutive arterial aneurism reported by Professor Lisco, and Dr. S. W. Gross, and two examples of arterio-venous aneurism described by Rufz, of Martinique, and Gabe, of Masarellos. In the first case the old operation of opening the sac was successfully performed, but such a procedure is too hazardous to be imitated. The patient of Dr. Gross was a negress, twenty-five years of age,

who was wounded by a pistol ball, which entered the neck opposite the upper border of the thyroid cartilage. Six months subsequently a small pulsating tumor was perceived just above the bifurcation of the common carotid, which rapidly increased until it measured eight inches transversely by five inches from above downwards, and formed an extensive swelling, the external features of which are depicted in the adjoining sketch, fig. 340. The common carotid was ligated in July, 1868, and in two months the tumor had diminished at least two-thirds. At the expiration of one year not a trace of it remained.

In the case of Gabe, the tumor, of the size of a nut, was seated near the lobule of the ear, and was caused by a sabre wound. It was treated unsuccessfully by Chelius, first by compression and afterwards by ligation of the common carotid, but was finally cured by Stroymeyer by the old operation.

The *temporal artery* has never, so far as I know, been the subject of spontaneous aneurism, but an aneurism of this vessel is occasionally met with as a result of external injury. In 1868, Dr. Macnamara, of Dublin, showed me a tumor of this kind, in a man thirty years of age, on the anterior branch of the temporal artery, caused by the scarificator in cupping; and cases of aneurism of this trunk or of its offsets have also been observed by Petrequin, Decès, Malgaigne, Frestel, and Pavesi.

The tumor, rarely exceeding the volume of a pigeon's egg, is usually of a spherical shape, and situated just in front of the ear, where it can nearly always be readily distinguished by its history, by its firm consistence, by its pulsation, and by its peculiar whiffing sound. The only two diseases with which it might be confounded are cystic tumors of the parotid region and aneurism of the middle meningeal artery, attended with absorption of the walls of the cranium, the swelling thus presenting itself directly beneath the common integument.

For the cure of this disease two procedures may be employed; the one consists in exposing and tying the temporal artery at the cardiac side of the tumor, as in the ordinary Hunterian operation, and the other in laying open the sac, and, after having turned out its contents, securing the vessel above and below. The former method, when practicable, should always be preferred, as it is not only more simple, but less liable to be followed by a disfiguring cicatrice.

Gamma saw an aneurism in the *facial* artery, near the commissure of the lips; Hoefnagels, in the interior coronary; Boyer and Klaving, in the posterior auricular; Giehrl and Agnew, in the occipital; Pancoast, in the stylo-mastoid; Rutz and Heyfelder, in the inferior dental; and Castle, Herapath, Tierlinck, and I myself, in the palatine. In nearly all of these cases the tumor was of small size, and owed its origin to external injury. In the case recorded by Castle the aneurism was caused by the pressure of the plate of artificial teeth.

The *middle meningeal artery* has, in a few instances, been the seat of aneurism, the result, apparently, of external injury. The nature of the disease can be recognized only when the tumor, causing absorption of the walls of the cranium, appears externally under the temporal muscle. A case has been related in which an aneurism of this vessel, making its way into this situation, was mistaken for a common cystic tumor of the scalp. As there was no pulsation, the surgeon cut boldly into the swelling, and found, to his dismay, that it was filled with blood. After repeated but fruitless efforts to arrest the hemorrhage, the patient expired. The dissection showed that the disease had been an aneurism of the middle artery of the dura mater. Had the real nature of the case been suspected in time, the proper remedy would have been ligation of the external carotid.

Some of the branches of the external carotid artery have occasionally, though rarely, been the seat of *arterio-venous aneurism*. In a case recorded by Langier, the abnormal opening existed between the posterior auricular artery and its satellite vein. A similar example has been reported by Broca; and Moore met with one in which a communication was established between the temporal artery and the accompanying vein.

ANEURISM OF THE INTERNAL CAROTID AND ITS BRANCHES.

Aneurism of the internal carotid has been observed only in a few instances, its deep situation at the side of the neck and its exemption from ossific and fatty degeneration serving to protect it from this disease. The diagnosis must be obscure. The tendency of the tumor is to extend inwards towards the pharynx, as there is much less resistance here than in any other direction, the only opposing obstacles being the constrictor muscle, some lax connective tissue, and the mucous membrane. The consequence is that more or

less prominence exists in the throat, attended with pain and pulsation, and closely simulating an abscess of the tonsil. The treatment is the same as in ordinary carotid aneurism.

A remarkable case of aneurism of this vessel has been recorded by Mr. Syme. The patient, a woman aged sixty, had had a tumor for about five months in the throat, in the usual situation of abscess of the tonsil. It had attained about the size of a large walnut, exhibited a diffused appearance when viewed through the mouth, and pulsated in a strong and characteristic manner in every portion of its extent. The ligation of the common carotid artery diminished, but did not completely arrest, the throbbing. The woman died in thirty hours after the operation, without any assignable cause. Had a less careful surgeon had the management of this case, he might probably have punctured the tumor under the supposition of its being an abscess, and thus instantly hurled his patient out of existence, much to his own discredit and that of the profession.

Aneurism of *the ophthalmic artery* is rare, both as a traumatic and as a spontaneous affection. The former, caused by various kinds of external injury, is liable to be followed by excessive enlargement of the structures of the orbit with protrusion of the eye. A number of cases of spontaneous aneurism of this artery are upon record, in only a few of which, however, the nature of the disease has been verified by dissection. Aneurism by anastomosis is also sometimes met with. The progress of aneurism of the ophthalmic artery is usually slow, and the symptoms are always characteristic. The proper remedy is ligation of the common carotid artery as early in the disease as possible, before there is any serious structural change in the parts. In anastomotic aneurism, a cure has occasionally been effected with injections with perchloride of iron; and lately several cases have been successfully treated by digital compression of the carotid. For further information on pulsating tumors of the orbit, the reader is referred to the affections of the orbit in the second volume of this work.

Of aneurism of the *supraorbital artery* only a few cases have been recorded. It is always produced by a wound or rupture of the vessel, and is readily recognized by its history, by the rounded or ovoidal shape of the tumor, and by the concomitant thrill and pulsation. The proper remedy is incision of the sac, with ligation of the artery. In an instance observed by Raoult Deslongchamps, a cure was promptly effected by an injection of perchloride of iron.

In the Transactions of the Academy of Medicine of Leipsic, mention is made of a case of aneurism of the *frontal artery*, and three other examples have been recorded, respectively, by Velpeau, Brodie, and Godichon. In the one observed by the latter, the tumor was of a pedunculated form, and larger than an ordinary thumb.

De Haen is said to have met with an aneurism in the dorsal artery of the nose; but it is questionable whether the lesion was anything more than an inordinate dilatation of that vessel.

Anterio-venous aneurism of the extracranial portion of the internal carotid artery is extremely rare. Instructive cases of it have been reported by Bérard, Desparanches, Joret, and Giraldès, all caused by external injury. One instance has been observed in which it was occasioned by a wound inflicted in opening an abscess. In two of the cases here referred to, the carotid artery, as was shown by the dissection, communicated with the internal jugular vein, and a well-marked aneurismal pouch existed between the two vessels. The injury was produced in two cases by a ball, in one by a particle of lead, and in the fourth by a shoemaker's knife. In the case of Giraldès the projectile was found in the aneurismal sac. The symptoms and treatment are the same as in arterio-venous aneurism of the common carotid.

INTRACRANIAL ANEURISM.

Intracranial aneurism possesses little interest in a surgical point of view. Of 85 cases, analyzed, in 1869, by Dr. James H. Hutchinson, of this city, nine occurred under twenty years of age, twelve between twenty and thirty, thirteen between thirty and forty, fourteen between forty and fifty, nineteen between fifty and sixty, eight between sixty and seventy, nine between seventy and eighty, and one between eighty and ninety. Of the 85 cases, 48 were males and 32 were females, the sex in five not being given. The basilar artery was the seat of the aneurism in 25 cases, the middle cerebral in 26, the internal carotid in 10, and in the remaining cases the smaller vessels. From an examination of 142 cases, Professor Bartholow, in 1872, found that the basilar was affected in 40, the middle cerebral in 41, and the internal carotid in 23. The disease may be the result of external injury, as a blow or fall on the head, or of syphilis, but more generally it arises

without any assignable cause. The aneurism, which is not always distinctly sacculated, is usually confined to one artery, and ranges in volume from that of a pea up to that of a pullet's egg. The vessels of the brain seldom exhibit any evidence of disease; but as the aneurism advances, the cerebral substance is displaced and disorganized, one of the most frequent lesions being softening. The cranial bones rarely suffer.

The most reliable symptoms are apoplexy and hemiplegia, buzzing noises in the ears, deafness, dizziness, vertigo, epileptiform convulsions, and pain in the head, either circumscribed or diffused, intermittent or continued, increased by motion, and accompanied by peculiar morbid sensations. These symptoms may come on suddenly, without any premonition, or, as is more frequently the case, arise gradually and almost imperceptibly. The diagnosis is always very obscure. In a few instances, the nature of the disease has been detected by a loud, rough, or whizzing noise on one side of the head, heard by the patient, and distinguished by auscultation.

Death may be produced, first, by the sudden rupture of the sac, and the escape of its contents into the surrounding parts; secondly, by long-continued irritation; and, lastly, by disorganization of the cerebral substance. Of these different terminations, the first is by far the most frequent, it having occurred in 49 of the cases collected by Dr. Hutchinson.

Very little can be effected by treatment. When the diagnosis can be satisfactorily determined, the carotid artery should be tied on the affected side, as was done successfully in a case of this disease by Mr. Coe, of Bristol, England, and in one by Mr. Berkeley Hill, of London.

ANEURISM OF THE VERTEBRAL ARTERY.

Aneurism of this artery, both spontaneous and traumatic, is extremely uncommon, a circumstance no doubt due to the deep situation of this vessel and to its freedom from ossification. In two very interesting cases of this disease, described by Ramaglia, of Naples, and South, of London, the diagnosis was so obscure that the true nature of the disease was not detected until after death. In both the common carotid was tied, without, of course, any benefit. In the former, which was an example of traumatic aneurism, situated behind the left ear, the operator, finding that the deligation did not arrest the pulsation, removed the ligature and treated the case upon general principles, death occurring soon after. In the other instance, in which the carotid artery could be distinctly traced over the tumor, this vessel was also tied under the supposition that it was the seat of the swelling. The tumor, however, rapidly increased, and in a fortnight after caused death by bursting into the trachea. Dissection showed that it was an aneurism of the vertebral artery, situated between the transverse processes of the fourth and fifth cervical vertebræ.

Moebus, a German surgeon, has reported a case of aneurism of the vertebral artery, the result of a wound of the neck, in which a cure was effected by compression and the use of ice.

ANEURISM OF THE INTERCOSTAL ARTERIES.

Aneurism of these arteries is exceedingly uncommon; and the few cases of it upon record are interesting rather as showing the errors of diagnosis committed by surgeons, than as facts illustrative of the history of the nature, progress, and termination of the disease. Dr. Schuster, of Lippe-Detmold, met with a case of caries of the fourth rib in which the corresponding intercostal artery was perforated, the blood which had escaped from the vessel being contained in a distinct sac. A case of aneurism of the intercostal artery, consequent upon a fracture of the rib, has been recorded by Dr. Uhde, of Brunswick. Dr. Martini, of Lübeck, opened an aneurism of the sixth intercostal artery, under the impression that it was a sebaceous tumor. It had apparently been caused by a contusion of the chest, and was associated with caries of the corresponding rib. The patient died. There are doubtless other cases of this affection upon record, but these are the only ones I can find. For the references I am indebted to Günther.

ANEURISM OF THE SUBCLAVIAN AND ITS BRANCHES.

Statistics prove that aneurism of the subclavian is nearly as frequent as that of the carotid. In Lisfranc's table the popliteal comes first, then the femoral, next the carotid, and then the subclavian, the latter having suffered in 16 cases out of 179. In the table

of Mr. Crisp, comprising 295 cases of external aneurism, the subclavian was concerned in 23, and the carotid in 25. The disease is more frequent in the right artery than in the left, in men than in women, and in the laboring than in the higher classes. The period of life during which most of the cases occur is between the thirtieth and fiftieth years. The disease may arise spontaneously, as the result of degeneration of the arterial tissues, but most frequently it is caused by external injury.

Mr. Alfred Poland, of London, who some years ago collected all the reported cases of subclavian aneurism, upwards of 120 in number, finds that 85 affected the right artery and 28 the left, only 2 cases involving both sides. Of the cases in which the sex was observed, 100 occurred in men and 11 in women. Of 79 male cases, in which the age is recorded, 24 occurred under forty years, 28 from forty to forty-nine, 17 from fifty to fifty-nine, and 10 over sixty years. The whole extent of the artery, from its origin to the axilla, was involved only in thirteen cases. The size of the aneurism ranged between a pigeon's egg and a child's head : 13 of the cases were traumatic, and 72 were idiopathic, the artery in 33 affording distinct proof of the existence of atheroma.

Although the disease may affect any portion of the artery, it is most frequent beyond the scalene muscles, a short distance before it becomes merged in the axillary. The form of the aneurism is generally globular or ovoidal, but cases are observed in which it has a singularly compressed appearance ; and, on the other hand, it may be remarkably lobulated, especially when it is very capacious, and extends deeply among the surrounding structures, which thus indent its surface. Its volume is seldom very large, unless it becomes diffuse, when it may attain an enormous magnitude, reaching nearly up to the angle of the jaw, pushing out the clavicle, overlapping the trachea, displacing the scapula, pressing backwards against the ribs and spine, and dipping into the cavity of the chest so as to force down the lung and impede respiration.

As the aneurism enlarges, it necessarily encroaches upon and compresses the neighboring parts, causing more or less pain, œdema, difficulty of respiration, dilatation of the veins of the neck, chest, and upper extremity, and a feeling of numbness and sometimes even partial paralysis. Loss of motor power in the corresponding arm and hand, diminution of temperature, contraction of the pupil, and increased action in the carotid artery, are occasional symptoms. The pulse at the wrist is often sensibly diminished, and sometimes totally absent. Originally small, deep-seated, circumscribed, indolent, and movable, the tumor generally steadily augments in volume, approaching, as it does so, nearer and nearer to the surface, loses its defined shape, becomes the seat of incessant pain, and at length contracts firm adhesions to the surrounding structures, identifying itself, as it were, with them. Examined with the ear and hand, it readily imparts to them the peculiar beat, thrill, and bellows sound so characteristic of aneurism in other regions.

Diagnosis.—The diagnosis of subclavian aneurism is sometimes extremely difficult, and several cases have been reported in which the vessel was ligated where no disease of the kind existed. The affections with which it is most liable to be confounded are aneurism of the innominate artery or arch of the aorta, abscesses, and various kinds of tumors, solid and cystic, benign and malignant. As these lesions are of frequent occurrence in this region, it is impossible for the surgeon to be too cautious in his examination of cases involving questions of diagnosis.

The history of the tumor and its situation at the side of the neck, just above the clavicle, generally afford important data in regard to the diagnosis. If the patient is under thirty years of age, it may almost certainly be assumed that the disease is not spontaneous aneurism, as there are probably not three well-authenticated instances on record in which the subclavian was thus affected at this early period. Aneurism of the innominate is situated lower down, and approaches nearer to the middle line, than aneurism of its subclavian division ; and in aneurism of the aorta, the tumor, although it may extend into the neck, rarely projects as far above the clavicle as in the lesion in question ; certainly not in its earlier stages, when alone a correct diagnosis can be of any avail in an operative point of view. If the case is seen soon after its commencement, before the tumor has attained any considerable bulk, a very good idea may often be formed as to the precise portion of the artery that is affected by it. Thus, for example, if the aneurism occupies the space immediately exterior to the sterno-cleido-mastoid muscle, and manifests a tendency to extend upwards into the neck, and downwards in the direction of the axilla, it may be assumed that it is seated upon the outer portion of the vessel beyond the scalene muscles. On the other hand, it may be concluded that it is connected with the inner portion of the artery if the tumor is placed under cover of the sterno-mastoid muscle, and is gradually making its way over towards the middle line, thus leaving the inferior triangle of the neck clear. It

may be added that in subclavian aneurism the tumor is less liable to encroach upon the windpipe and œsophagus than in innominatal and aortic aneurism, and hence there is generally much less cough, dyspnœa, and dysphagia in this than in the other affections. It is only, in fact, when the tumor is of great bulk, or when it happens, from the peculiarity of its position, to exert much pressure upon the pneumogastric, phrenic, and laryngeal nerves, that any serious symptoms of this kind will be likely to arise.

Progress.—Subclavian aneurism is always a serious disease, a spontaneous cure, although possible, as several cases upon record testify, being an extremely rare occurrence. In general, the disease progresses until it attains a certain point of development, when it terminates fatally, either by ulceration and hemorrhage, or by the induction of constitutional irritation. The sac may open externally, a not uncommon event, especially when it is invaded by gangrene; or it may burst into the pleura, lungs, trachea, or œsophagus; in either case, death takes place, either instantly or within a short time after the tumor has begun to give way. There are several cases on record in which the aneurism pointed in the axilla and on the shoulder, having completely eroded some of the upper ribs and the body of the scapula, the latter being scooped out so as to form a kind of bed for the accommodation of the sac.

Of 35 cases tabulated by Poland, in which no mechanical or surgical interference was adopted, 11 recovered, 23 died, and 1 was relieved. In 22 of these cases, 4 underwent a spontaneous cure, without any treatment whatever, while of the remaining 13, in which the patient was either bled or some internal remedy administered, 7 were cured, 5 died, and 1 was benefited.

Treatment.—The treatment of subclavian aneurism has hitherto been exceedingly unsatisfactory, and there is no probability, judging from the deep situation and intricate relations of the tumor, that much benefit will ever accrue from any mode of management that may be devised for its relief. Acupuncturation and electricity, from which so much benefit had at one time been anticipated, have likewise disappointed expectation. Some time ago a case was reported in which a cure was alleged to have been effected by galvanopuncture, but the example is a solitary one, and the procedure is of too problematical a character to merit serious attention. The measures which have hitherto proved to be the most promising are the plan of Valsalva, direct compression of the sac, and manipulation. In the event of the failure of these methods of treatment, of what resource can the surgeon avail himself in this unfortunate class of cases? Ligation of the affected artery is not only difficult, under any circumstances, from the position of the tumor and the intricacy of its anatomical relations, but is frequently absolutely impracticable on account of the diseased state of the artery, rendering it unable to support the ligature. Shall he adopt the operation of Dr. Mott, and secure the innominate, of which the subclavian, on the right side, is one of the main divisions? Here, again, obstacles meet him in every direction, for even if he should be so fortunate as to get his ligature around the vessel, which, however, is by no means always the case, he will find, by consulting the history of the operation, that every instance, with one exception, in which it has been performed has had a fatal termination. Nothing, therefore, is to be gained from this procedure. In short, the Hunterian principle of operation is hardly applicable to any case of subclavian aneurism. On the right side, we are not only obliged to encounter, as just stated, great difficulties in reaching the innominate artery, but in throwing a ligature around the vessel we effectually cut off a large and important supply of blood from the brain, thus greatly enhancing the dangers of the case.

The innominate artery has been tied for the cure of aneurism of the subclavian in 14 cases, and in 2 for hemorrhage. The results are subjoined in tabular form.

Ligation of the Innominate Artery.

No.	Operator.	Date.	Age	Sex	Disease.	Result.	Remarks.
1	Mott	1818	57	M.	Subclavian aneurism	Died on 26th day	Artery tied half an inch below its bifurcation; ligature separated on the 14th day; hemorrhage on the 9th, and again on the 23d day; death on 26th day. Ulceration of the artery, and want of occlusion.
2	Graefe	1822	...	M.	Subclavian aneurism	Died on 67th day	Ligature came off on the 14th day; death from hemorrhage.
3	Norman	1824	...	M.	......	Died	Death from pericarditis in sixty hours.
4	Arendt	1824	36	M.	Subclavian aneurism	Died on 8th day	Cause of death inflammation of the aneurismal sac and of the pleura and lung.

No.	Operator.	Date.	Age	Sex	Disease.	Result.	Remarks.
5	Hall	1830	45	M.	Subclavian aneurism	Died on 5th day	Artery morbidly adherent, dilated, soft, and friable ; torn in the attempt to separate it, at two points, between which the ligature was applied ; copious hemorrhage during operation ; plugging of the wound ; participation of the aorta and carotid in the disease.
6	Bland	1832	31	M.	Subclavian aneurism	Died on 18th day	Ligature placed around the artery near its bifurcation ; hemorrhage on the 17th day, proving fatal on the 18th ; the innominate and carotid closed by solid clots ; the subclavian still open.
7	Lizars	1837	30	M.	Subclavian aneurism	Died on 21st day	Ligature separated on the 17th day ; pleuritis ; death caused by repeated hemorrhages ; twenty ounces of coagulated blood at the root of the neck ; arteries imperfectly closed.
8	Hutin	1842	26	M.	Hemorrhage after ligature of subclavian	Died in 12 hours	Tied for secondary hemorrhage, after subclavian had been secured for wound of the axillary.
9	Gore	1856	52	M.	Subclavian and axillary aneurism	Died on 17th day	Death from hemorrhage ; aneurism contracted and filled with coagulum. Artery cut through by ligature. Pus in subclavian vein and anterior mediastinum.
10	Cooper	1859	...	M.	Subclavian and carotid aneurism	Died on 9th day	Upper end of sternum and clavicle removed to facilitate operation ; dyspnœa and retention of urine ; pus in right kidney ; death probably from uræmia and pyæmia.
11	Cooper	1869	31	M.	Subclavian aneurism	Died on 41st day	Ligature, applied an inch from the aorta, detached on the 18th day ; patient did well for three weeks, when hemorrhage occurred, and finally caused death. Upper end of sternum and clavicle removed.
12	Pirogoff	1864	46	M.	Subclavian aneurism	Died in 24 hours	Cause of death œdematous suppuration of sheath of artery, extending to the mediastinum and pericardium.
13	A. W. Smyth	1864	...	M.	Subclavian aneurism	Recovery	Ligature applied to innominate a quarter of an inch below point of division, and at the same time to carotid one inch above origin. Hemorrhage on 15th day, controlled by plugging wound with small shot and ligature pulled away. Hemorrhage recurred on 33d and 51st days, and vertebral artery tied on 54th day. Patient died at end of ten years of the original aneurism, which again formed by the reverse collateral circulation.
14	Lynch	1867	23	M.	Hemorrhage from gunshot wound of internal carotid and vertebral arteries	Death	Common carotid ligated one month previously. Death from hemorrhage on 12th day, when the ligature was found lying loose in wound. Partially organized clots in cardiac end of artery. Close to point of ligation an anomalous branch was given off, which, by keeping up the circulation on the cardiac side of ligature, permitted the clot to be loosened on its separation.
15	A. B. Mott	1868	...	M.	Subclavian aneurism	Died on 23d day of hemorrhage in thorax.	Carotid was tied at same time ; sac burst into pleural cavity.
16	Bickersteth	1868	40	M.	Subclavian aneurism	Death on 6th day from hemorrhage	Artery was first secured by lead wire, which was replaced on second day by two ligatures, one above and the other below the wire. Clot firm in innominate on cardiac side ; subclavian occluded ; carotid open, and hence seat of fatal hemorrhage.

All the cases in the above table, except six, proved fatal from hemorrhage of the wound, caused by the want of occlusion either of the ligated artery, or of the carotid and subclavian. It will be observed that Graefe's patient survived upwards of two months. I purposely exclude from the table the cases which are usually referred to as having occurred in the practice of Dupuytren and Bujalski, not considering them as sufficiently well authenticated to entitle them to a place in it. I also reject from it several reported cases in which the operation of ligating the innominate artery was commenced but not completed.

Dr. Peixotto, of Portugal, in 1851, surrounded the innominate artery with a ligature, on account of secondary hemorrhage from the common carotid, which had been ligated three weeks previously. The ligature, however, which was a precautionary one, was not tightened, but applied merely so as to flatten the vessel. The patient made a good recovery. Such an operation can hardly be regarded as a true case of deligation of the innominate artery. The cure was doubtless effected by the ligation of the other vessel.

Mr. Key, of London, in a case of aneurism of the subclavian, found it impracticable to apply a ligature to the innominate, in consequence of the volume of the tumor, and the diseased condition of the latter vessel. The patient was seized soon after the operation with symptoms of pulmonary distress and exhaustion, and died on the twenty-third day.

The operation of ligating the innominate artery is one of no inconsiderable difficulty even in the dead subject, but in the living the perplexity is greatly increased by the proximity of the aneurism, by the presence of glandular swellings, and, above all, by the manner in which the parts at the root of the neck are matted together by plastic deposits, rendering it thus exceedingly troublesome to separate them. These embarrassments were experienced in a striking degree by Dr. Hall, of Baltimore; he had great difficulty in isolating the vessel, and, in attempting to do so, tore it at two points, ligating it afterwards between them. Hemorrhage occurred at the time, but was checked by plugging the wound. Another obstacle to successful deligation is disease of the vessel, consisting either in a morbid dilatation, or in a softened and lacerable condition of its coats. Unforeseen difficulties were present in more than one-fourth of the cases in which ligation of the artery has been attempted, compelling the operators to desist, notwithstanding their great dexterity and profound knowledge of the anatomy of the neck.

Mr. Porter, of Dublin, in 1831, attempted to tie this artery on account of aneurism, but was obliged to desist on account of its diseased condition. The tumor, nevertheless, gradually disappeared, and the patient, a man forty-seven years of age, finally recovered.

Dr. Hoffman, of New York, in a case of subclavian aneurism in a man sixty-three years of age, cut down upon the innominate artery with the design of applying a ligature to it, should he be unable to ligate the subclavian; but, as the vessel was found to be much enlarged, it was deemed inexpedient to proceed any further. The operation was performed in October, 1839, and death occurred in January, 1840.

The proposal to ligate the innominate artery originated with Allan Burns, from a conviction that the circulation in the head and upper extremity could be maintained without the agency of this vessel, and that it could be easily enough exposed by tracing it downwards towards the aorta, by a careful and patient dissection, the head being at the time bent well back. It remained, however, for Dr. Mott, in 1818, to put the suggestion to the test of experiment upon the living subject; and, although the operation had an unfavorable issue, the man dying, as has already been stated, on the twenty-sixth day, we cannot but admire the genius which could plan, and the intrepid skill which could execute, so daring and brilliant a feat. The case was one of subclavian aneurism above the clavicle, and the design had been to apply the thread to the latter vessel, but, after exposing it on the tracheal side of the scalene muscle, it was found that its tunics were too much diseased to bear the pressure of the ligature, and he accordingly tied the innominate in its stead.

It will thus be seen that the only successful case of ligation of this vessel, is that of Dr. Smyth, who tied both the innominate and the carotid at the same time, and the vertebral fifty-four days after, an expedient which alone saved the patient's life. Alexander B. Mott also tied the innominate and carotid simultaneously, but the man died on the twenty-third day, from the rupture of the aneurism into the pleural cavity. All the cases recorded in the table were males, most of them under forty years of age. In fourteen out of the sixteen the operation was performed for the relief of subclavian aneurism. In the cases of Lizars and Valentine Mott, an anomalous branch, probably the middle thyroid, arose from the innominate near the ligature and probably interfered with the success of the operation. Dr. John A. Wyeth, in referring to this vessel, states that he met with it five times in thirty-four consecutive dissections.

LIGATION OF THE SUBCLAVIAN ARTERY ON ITS TRACHEAL ASPECT.

This vessel is sometimes ligated in the first portion of its course for aneurism between or beyond the scalene muscles. The subjoined table, comprising eleven cases, will serve to place the subject in its true light.

No.	Operator.	Sex.	Age.	Result.	Remarks.
1	Colles	M.	33	Death	In this case there was only a space of three lines between the sac and the bifurcation of the innominate. The patient died of hemorrhage on the fourth day.
2	Mott	F.	21	Death	The patient died on the eighteenth day, of hemorrhage.
3	Hayden	F.	57	Death	Death on the twelfth day, from hemorrhage.
4	O'Reilly	M.	39	Death	The patient died on the thirteenth day, of hemorrhage.
5	Partridge	M.	38	Death	Fatal on the fourth day, from pericarditis and pleurisy.
6	Liston	M.	32	Death	The patient died on the thirty-sixth day, of hemorrhage.
7	Auvert	...	...	Death	Fatal hemorrhage on the twenty-second day.
8	Auvert	...	...	Death	Fatal hemorrhage on the eleventh day.
9	J. K. Rodgers	M.	42	Death	Fatal hemorrhage on the fifteenth day.
10	Arendt	M.	...	Death	Death from exhaustion on fifth day; no hemorrhage.
11	Bayer	M.	21	Death	Fatal hemorrhage in twenty-four hours.

The result in all the above cases, except two, was death by hemorrhage, notwithstanding the undoubted ability and skill of the operators, comprising some of the most illustrious names in surgery. Should this fact not be sufficient to deter practitioners from repeating the operation, or should they continue in their efforts to save life until some one, more fortunate than the rest, shall succeed in finding an exceptional case? The case of Dr. J. Kearney Rodgers, of New York, in which the artery was secured on the left side on account of an aneurism, is of the deepest interest in this respect, as showing that, although the patient finally perished from hemorrhage, yet the ligated vessel was completely closed by an adherent coagulum. The cases of Cuvellier and Parker, and one of Liston are excluded from the table, since they were examples of simultaneous ligation of the carotid and subclavian arteries; as are also those of Ayres and Bullen in which the subclavian was tied for shot wounds, and the case of Kuhl in which the carotid and subclavian arteries were ligated for a vascular tumor of the frontal region.

Until the operation of Dr. Rodgers, it was universally regarded as impracticable to ligate the left subclavian artery on the inside of the scalene muscles, such being the intimate relation of the vessel in this situation to the sac of the pleura, the carotid artery, internal jugular vein, pneumogastric nerve, and thoracic duct. It had been thought that, from the severe injury which would necessarily be inflicted upon the surrounding structures during the operation, violent and fatal inflammation must be the speedy and inevitable consequence. At all events, no one had yet been found ingenious enough to devise, and bold enough to execute, such an enterprise. Although it is not likely that the operation will soon be repeated, the case in question deserves notice here as a matter of surgical history, if nothing more.

The patient was a man, aged forty-two, who, in lifting a heavy weight, upwards of a month previously, was suddenly seized with an aneurism of the left subclavian artery. At the time of his admission into the New York Hospital, the tumor could be seen above the clavicle, about the size of a small hen's egg, extending outwards towards the shoulder, and inwards towards the sterno-cleido-mastoid muscle, by the outer border of which it was considerably overlapped. The operation was performed on the 14th of October, 1845. Two incisions were made; one, three inches and a half in length, along the inner border of the sterno-mastoid muscle, terminating at the sternum, and dividing the integument and platysma-myoid muscle; the other, two inches and a half in length, extending horizontally over the inner extremity of the clavicle, the two meeting at a right angle near the trachea. Several small veins having been ligated, and the flap thus formed dissected up, the sternal portion with half of the clavicular of the mastoid muscle was divided upon a grooved director, a procedure which fully brought into view the sterno-hyoid and omohyoid muscles and the deep-seated jugular vein, all covered by the cervical fascia. A part of the aneurismal sac was also in sight, overlapping a considerable portion of the anterior surface of the scalene muscle, upon which the operator could distinctly feel the phrenic nerve. By digging with the handle of the knife and fingers, the deep cervical fascia was now divided close to the inner edge of the scalene muscle,

when, after a little search, the subclavian artery was easily discovered as it passed over the first rib, pressure upon this portion readily arresting the pulsation of the tumor. The next step of the operation consisted in passing the ligature around the vessel without injury to the pleura and thoracic duct, but this proved to be one of extreme difficulty, owing to the great narrowness and depth of the wound, the latter nearly equalling the length of the forefinger. This, however, was at length successfully accomplished by means of an aneurismal needle with a movable point, carried from below upwards. The moment the ligature was tied all pulsation in the tumor ceased, and the patient, if not entirely comfortable, made no complaint of any kind.

The wound became somewhat erysipelatous after the operation, but, on the whole, the patient got on well until the 26th of October, when, on changing his position in bed, hemorrhage supervened, and, continuing to recur at various intervals, destroyed him on the fifteenth day. On dissection, the wound was found to be filled with clotted blood, beneath which the artery had been completely divided by the ligature, which lay loose close by. The stump of the subclavian, between the aorta and the point of ligation, was about an inch and a quarter in length, and thoroughly impervious to air and liquids, its caliber being occupied by a solid and firmly adherent coagulum. The distal extremity of the subclavian contained a soft, imperfect clot, while the vertebral artery, which was given off immediately at the site of the ligature, was almost patulous, and had evidently been the seat of the hemorrhage which caused the patient's death. The aneurismal sac, the size of a small orange, was completely blocked up with coagula. The thoracic duct was uninjured, but the pleura at the bottom of the wound was found to be extensively lacerated, and through the opening thus formed a large quantity of blood had passed into the left cavity of the chest.

In reflecting upon this interesting case, Dr. Rodgers regretted that he had not secured the vertebral artery and also the thyroid axis, believing that this would have effectually prevented the fatal hemorrhage. Professor Willard Parker, acting upon this suggestion, in September, 1863, tied the left subclavian artery on the inside of the scalene muscles, along with the common carotid and vertebral, on account of subclavian aneurism. The case progressed well until the tenth day, when there was a slight hemorrhage. The ligature separated from the vertebral on the twelfth day, from the carotid on the fourteenth, and from the subclavian on the twenty-fourth. Death occurred at the end of the sixth week, from hemorrhage of the distal side of the subclavian.

In examining the tables of Dr. Wyeth, I find that ligation of the second or third portion of the subclavian artery has been practised for the cure of aneurism of that vessel 38 times, with 18 recoveries and 20 deaths. Of the cures, seventeen were examples of subclavio-axillary vessel, while one was an example of pure subclavian aneurism. In two instances partial division of the scalene muscle was required to give more room for the operation. The average period at which the ligature separated, according to Mr. Poland, who has recorded twenty-one cases, was 32 days, the minimum 15, and the maximum 96. The latter was the remarkable case of Dr. J. M. Warren, in which the subclavian artery was successfully tied on the outside of the scalene muscles for an aneurism of this vessel situated above the clavicle.

All of the 20 fatal cases were subclavio-axillary aneurisms except one, and in one partial division of the scalene muscle was necessary. Nine deaths were due to hemorrhage, two to coma, four to exhaustion, and three to lung complications, the cause being unknown in two.

Aneurism of the subclavian has also been treated by the distal ligature, but with the most unpromising results. Thus, ligature of the carotid proved fatal on the fourth day in the hands of Mr. Butcher, while ligation of the axillary, performed by Dupuytren, Schuh, and Canton, was equally unsuccessful. In a case of aneurism of the first part of the subclavian, Pétrequin also tied the axillary artery. The tumor continuing to pulsate, the sac was punctured, and eight or nine drops of a solution of perchloride of iron were thrown in, the brachio-cephalic trunk being compressed during the injection and for ten minutes afterwards. The next day all pulsation had ceased in the tumor, but the patient died of hemorrhage at the place of ligature twelve days after its application. In 1874 Dr. Toland, of San Francisco, ligated the third portion of the subclavian artery with two threads for an aneurism as large as the fist. The ligatures came away on the twentieth day, and neither pulsation nor bruit could be detected in the tumor at the end of six weeks.

In 1838, Mr. Liston secured the common carotid and the first portion of the subclavian, in a tailor, thirty-one years of age, in whom galvano-puncture had been unsuccessfully

employed. Death resulted from hemorrhage on the thirteenth day. In a case of traumatic subclavian aneurism, from a bayonet-thrust at the battle of Magenta, in a dragoon, aged twenty-one years, Cuvellier performed a similar operation, followed by hemorrhage on the tenth day.

It thus appears that the treatment of subclavian aneurism by the ligature is most unsatisfactory. Of 72 cases, 52, or 72.22 per cent., proved fatal, the only successful issues having been obtained in one case out of fourteen of ligation of the innominate, in two cases out of five of ligation of the second portion of the subclavian, in sixteen cases out of thirty-three of ligation of the third portion of the subclavian, and in one case out of six of distal ligation. Under these circumstances it is questionable whether ligature of the innominate, or of the first portion of the subclavian should be repeated. As pointed out by Wyeth ligation of the second portion of the left subclavian is as safe as that of the third division, so that it may be tied when the necessity exists.

Mr. George H. Porter, of Dublin, in 1867, treated unsuccessfully a case of aneurism of the right subclavian artery by acupressure of the axillary artery, followed, at the end of about five weeks, by direct pressure of the innominate artery, death occurring ten days after the latter operation, from secondary hemorrhage caused by slight gangrene of the vessel at the site of the compression.

Benefit may occasionally arise in subclavian aneurism from *manipulation* of the tumor, as practised by Fergusson; some of the clots detached in the operation may accidentally find their way into the distal extremity of the vessel, and thus occlude its caliber along with the interior of the aneurismal sac. In a disease so desperate as this, in which every expedient hitherto devised has been tried in vain, any suggestion that holds out the least possible chance of relief is worthy of trial. Of seven cases that were subjected to this mode of treatment, three died, one was unsuccessful, and three recovered, the latter having been reported by Fergusson, Little, and Pemberton.

Compression, whether digital or mechanical, proximal or distal, of the artery leading to or from the sac, has been attempted in several instances, but, from the difficulty of applying and maintaining pressure, it has, with three exceptions, been uniformly attended with failure. Mr. Poland has narrated a case of subclavian aneurism, of the size of a filbert, occurring in a man, forty-four years of age, cured by digital compression of the artery on the cardiac side of the tumor, the thumb having been placed over the vessel at the outer border of the scalene muscle. It was kept up for ninety-six hours, with a few minutes' intermission, when the tumor was much harder and smaller, although it still pulsated slightly. At the expiration of a week the pulsation had ceased, and the tumor subsequently entirely disappeared. The course of the artery was high above the clavicle, having, probably, been lifted up by a cervical rib, which thus afforded a good point for counterpressure. Digital compression, combined with the subcutaneous injection of ergotine, proved successful in the hands of Dutoit; but Mr. Willett lost his patient from rupture of the sac, which had at the same time been subjected to direct compression. Dr. Warren Stone applied compression with the finger on the distal side of the sac for thirty-nine hours; but the pulsation did not cease entirely until the expiration of nine months. In several cases the measure had to be abandoned in consequence of the severe suffering to which it gave rise.

Moderate direct compression of the sac has been successfully employed in four instances, collected by Mr. Poland, and is worthy of more extended trial. In two cases in the hands of Dr. J. M. Warren, too far advanced for ligation, a cure was effected by direct compression, aided by the application of bags of ice. The tumor, in one of the cases, suppurated and partially discharged its contents. In a fifth case death ensued.

Galvano-puncture has effected one cure in five cases, but this mode of treatment is too dangerous to deserve imitation.

Injection of the sac with coagulating fluids has been practised at least three times. In the case of Dr. Mott, immediate death ensued. The case of Petréquin, above referred to, was a failure, while the third case terminated fatally from hemorrhage.

The introduction of horsehair, to which Dr. Levis resorted in 1873, was followed by death on the thirty-fourth day.

Finally, amputation of the arm at the shoulder-joint, with distal ligation of the axillary artery on the face of the stump, may be resorted to, as originally suggested by Fergusson, and successfully practised by Spence, in 1864. The patient, an engineer, thirty-three years of age, left the hospital on the forty-fourth day in excellent health, but four years subsequently death ensued from supposed internal aneurism. In three other cases, in the hands, respectively, of Mr. Heath, Mr. Holden, and Mr. Smith, the measure failed; but

in the case of Mr. Rose, in which the common carotid artery was also ligated, the tumor, at the end of three weeks, was reduced one-third, and the patient was free from suffering.

Arterio-venous aneurism of the subclavian artery is extremely uncommon. Sanson met with an example, the result of a bullet wound, and Baron Larrey has recorded two cases, produced, respectively, by a sabre-thrust and gunshot injury. In none of these cases did the tumor give rise to serious inconvenience. In an instance of this kind under my own observation during the last six years, the only annoyance experienced is from the noise of the tumor.

ANEURISM OF THE TRANSVERSE CERVICAL ARTERY.

A case of aneurism of this artery, the only one of which I have any knowledge, was reported, in 1869, by Mr. Pick, in the Transactions of the Pathological Society of London. The tumor, situated on the left side of the neck, just above the clavicular origin of the sterno-mastoid muscle, was of the size of a walnut, soft and fluctuating, with forcible pulsation, and a peculiar upheaving of the entire mass as if the sac lay merely over an artery instead of forming a component part of it. There was scarcely any audible bruit. The tumor took its rise close to the origin of the transverse cervical artery, which in this instance came off directly from the subclavian, and not, as is usually the case, from the thyroid axis. It rested upon the subclavian vessels, was partially covered by the clavicular attachment of the sterno-mastoid muscle, and was completely filled with a firm, semitransparent clot, intimately adherent to the walls of the sac, but without any laminated arrangement. All the coats of the artery seemed to have been involved in the aneurism, the communication between them having been established by a small orifice. The patient was a soldier, forty-five years of age, recently discharged from the army, and the tumor had been noticed for the first time only three weeks before death, which was caused by phthisis. Direct pressure with a pad and bandage was kept up for some time, after which iodine was daily applied with marked advantage, although the pulsation and the upheaving appearance continued to the last. The diagnosis was obscure.

ANEURISM OF THE SUBSCAPULAR ARTERY.

Of spontaneous aneurism of this vessel I do not find a solitary instance upon record; a circumstance easily accounted for, by the deep situation of this vessel, its small size, and the infrequency of the degeneration of its tunics. Of the traumatic form of the lesion a case was reported in 1874, by Dr. Monmonier, of Baltimore, in a man twenty-one years of age, who, sometime previously, had fallen down a flight of stairs, the arm being thrown suddenly upwards and violently extended so as to rupture the vessel. The tumor, which was of considerable size, occupied the left axilla, was of a firm, fibroid consistence, and destitute of pulsation. Fearing that the hemorrhage might prove troublesome, Dr. Monmonier tied the subclavian artery in the third part of its course, and then laid open the tumor and turned out the clots. Recovery occurred without any accident.

ANEURISM OF THE AXILLARY ARTERY.

Aneurism of the axillary artery is less frequent than that of the subclavian. In 364 preparations of aneurism in the London museums, examined by Mr. Crisp, including 249 of the aorta, the axillary artery was affected only in 8. In 551 cases analyzed by him from different sources, including 234 cases of aneurism of the aorta, 18 only were of the axillary artery.

The disease is most frequent in men, between the ages of thirty-five and fifty. It is very often of traumatic origin. In an instance recorded by Roux it was caused by the pressure of an exostosis. The volume of the tumor ranges from an egg to that of a child's head, the average being that of a fist. Arterio-venous aneurism of the axillary vessels is very uncommon.

Symptoms.—The symptoms of axillary aneurism are generally so well marked as to render it impossible to mistake their character. When the disease arises spontaneously, or without any assignable cause, it may exist for several months without attracting any particular notice, and the same thing occasionally occurs when it results from external violence, as a blow or strain. Generally, however, the tumor rapidly augments in bulk,

and produces such a train of phenomena as to lead at once to its detection. Of these, one of the earliest, and at the same time most unpleasant, is the sense of fatigue or uneasiness in the affected part arising from the pressure on the axillary plexus of nerves. This symptom is usually succeeded in a few weeks, sometimes, indeed, in a few days, by a feeling of pain, which is always in direct ratio to the size of the aneurism, being comparatively slight when it is small, and more or less intense when large. Nor is the pain confined to the site of the disease; in most cases it radiates from it, as from a common centre, in different directions, outwards into the shoulder, downwards along the arm, and upwards into the neck. Pressure, severe coughing, the recumbent posture, and the weight of the limb, greatly increase it. Numbness of the shoulder, chest, and arm, is another symptom which generally manifests itself at an early period of the disease, and is never absent when the tumor has acquired considerable magnitude. It is always very distressing to the patient, is greatly aggravated by pressure on the swelling, and commonly extends to the ends of the fingers. Indeed, it is here that the sensation in question is often most keenly felt.

The pulsation of the tumor, at first faint and scarcely perceptible, becomes very distinct during the progress of the disease, so that it cannot only be felt by the fingers, but seen at a considerable distance; sometimes, indeed, ten or twelve feet from the patient. On applying the ear or the stethoscope to the tumor, the blood is found to rush into it with more or less violence, producing a peculiar thrill, or whizzing noise, synchronous with the contraction of the left ventricle of the heart. In the early stage of the disease, the swelling is soft and elastic, and may readily be emptied by pressure; by degrees, however, it becomes firm, tense, and, in great measure, if not entirely, incompressible. In some cases, especially in those attended with great enlargement, there is considerable diminution of the temperature of the affected limb, with indistinctness, if not entire absence, of the pulse at the wrist, more or less cough, dyspnœa, and shortness of breathing. Occasionally the pulse is fully as strong as in the other arm, but irregular or intermittent, losing several strokes in a minute.

In addition to these symptoms, there is always, when the swelling is large, so much displacement of the clavicle as to render it difficult, if not impossible, to distinguish the pulsation of the subclavian artery, the vessel being deeply buried behind and below the bone. In some instances the collar-bone has been found to be considerably imbedded in the tumor, or partially removed by absorption. Another symptom, which, from its frequency, especially in the latter stages of the disease, requires mention here, is the swelling of the affected limb. This varies in degree in different cases, often extends from the shoulder to the ends of the fingers, and is usually of an œdematous character, pitting under pressure, and becoming aggravated by the dependent position of the part. When thus affected, the muscles lose their contractile power, and the motions of the extremity are proportionately impaired, or entirely annihilated. Sometimes, again, owing to the great magnitude of the tumor, the patient is unable to approximate the limb to the side of the chest. Finally, there is another phenomenon, which, as it is almost invariably present in the latter stages of axillary aneurism, I am disposed to regard as pathognomonic. I allude to the peculiar attitude of the patient, arising from the constant inclination of the head towards the affected side, and the manner in which he supports the corresponding arm; the object of both being evidently to prevent the tension which would otherwise be caused in the tumor. Under these circumstances, too, the countenance wears an anxious and distressed appearance, and, as the system always deeply sympathizes with the local affection, there is more or less derangement of the general health.

When the tumor is unusually bulky, it will necessarily greatly encroach upon the clavicle, forcing it upwards into the neck, and at the same time exerting severe pressure upon the subclavian artery, perhaps so much as to render it difficult, if not impossible, to distinguish the pulse at the wrist.

Diagnosis.—Notwithstanding that the symptoms of this disease are usually well marked, sometimes tumors of this description have been opened, under the belief that they were abscesses. For such an error no apology can be offered. Still, cases occasionally present themselves, although very rarely, in which it is extremely difficult, at first sight, to distinguish between this and other swellings in the armpit or subclavicular region. Enlarged lymphatic glands, adipose tumors, or sarcomatous growths, for example, if they chance to lie along the course of the axillary artery, might have its pulsation imparted to them, and thus create some doubt in regard to their real character. Under such circumstances, the facility with which the mass can be elevated or removed from the vessel, the absence of the peculiar whizzing sound, previously alluded to, as being generally present in aneu-

rismal disease, the slight pain and numbness in the part and in the corresponding limb, the continuance of the swelling on the application of pressure to the subclavian artery, and, above all, the history of the case, will generally be sufficient to establish the diagnosis.

In this disease the tumor may be situated either immediately below the clavicle, or in the axilla, properly so called. In the former case, it may not only elevate the clavicle, but extend up into the neck, beneath the bone, as far as the outer border of the scalene muscles. In the latter, it has been known to reach some distance down the arm, so as to compress the brachial artery and nerves, and prevent the approximation of the limb to the side.

Prognosis.—Axillary aneurism occasionally undergoes spontaneous cure, as in the instances reported by S. Cooper and Breschet. Such an occurrence, however, is extremely uncommon. Most generally, the disease, if left to itself, terminates fatally, either by rupture of the sac and exhausting hemorrhage, or by gangrene of the limb. Sometimes, although rarely, the tumor destroys life by inducing caries of the ribs and perforation of the pleura, followed by an escape of its contents into the cavity of the chest. In a case narrated by Mr. Guthrie, it was ascertained, on dissection, that the aneurism had forced its way into the right side of the chest by the destruction of a portion of the first five ribs, and had contracted adhesions to the upper lobe of the lung, into which it had gradually opened and discharged its contents, the man having spat blood more or less profusely for several weeks prior to his death. In a similar case mentioned by Dr. Neret, of Nancy, an aneurism, about the size of a large chestnut, communicated with a cavity of the volume of the head of a new-born infant in the upper part of the left lung. The man had been admitted into the hospital on account of hemoptysis.

Treatment.—Intermittent digital compression of the subclavian artery, as it passes over the first rib, should always be resorted to for this disease before recourse is had to the ligature, as it holds out considerable prospect of permanent relief. Thus, of 9 cases in which it was practised, 6 were cured. In one the compression was applied under chloroform, once for three hours and a quarter, and on another occasion for eight hours. In a second case it was maintained for six hours a day for six days. In two other successful examples, on the other hand, it was applied at intervals, respectively, for three months and six months. In the event of the failure of the measure, the only remedy is ligation of the subclavian artery, and the sooner this is done, the more likely will it be to succeed. The operation, however, should not be declined, even although gangrene of the sac has already commenced, provided there is nothing else to forbid it.

Mr. Syme laid open, with complete success, a spontaneous aneurism in this region, turning out its contents, and tying the axillary artery above and below the points of communication with the sac. As a means of safety, the subclavian was compressed by the finger of an assistant against the first rib, through an incision in the neck which divided the skin and fascia. By this procedure the circulation was so effectually controlled that there was hardly any hemorrhage. Few operators, unless possessed of the most consummate skill, would be willing to imitate the example of the Edinburgh surgeon, or not prefer the ligation of the subclavian artery on the outside of the scalene muscle.

In a case of axillary aneurism, the size of a child's head, the result of a gunshot injury received six years previously, under the care of Dr. C. C. F. Gay, of Buffalo, the tumor, previously pierced by a large trocar at the softest part, burst under the pressure of the fingers during the examination, followed by profuse hemorrhage. This was, however, speedily controlled by thrusting the hand through the rent, behind the clots, and seizing the axillary vessels. The subclavian artery was then compressed, and next tied at the junction of its second and third portions. On the ninth day secondary hemorrhage supervened, but was promptly arrested by plugging the wound with lint wet with Monsel's salt. The ligature came away on the seventeenth day after the operation, and in six weeks the patient was well, with the exception of slight paralysis of the arm.

Mortality.—Of 27 cases of axillary aneurism, which I analyzed in 1841 in the Western Journal of Medicine and Surgery, including one of my own, for which the subclavian artery had been tied, 17 recovered and 10 died, death occurring from the third to the thirtieth day, either from hemorrhage, gangrene of the arm, ulceration of the artery, pericarditis, pleurisy, or pneumonia. In one case it was caused by effusion into the brain, and in another, my own, by rupture of the aneurismal sac into the thoracic cavity. In the tables of Dr. Norris, showing the mortality in 69 cases in which the subclavian artery was tied for aneurism, including 9 of wounds of the axillary artery and 2 of tumors not aneurismal, although supposed to be so at the time, 36 recovered, and 33 died.

According to Professor Parker, the subclavian artery has been ligated 81 times, with

29, or 35.80 per cent. of deaths, for idiopathic and traumatic axillary aneurisms. Of 57 idiopathic cases, 21 died, while of 24 traumatic cases, 8 proved fatal. Le Fort has collected 97 cases of ligature of the third portion of the subclavian for wounds, or for diffused and circumscribed aneurisms of the axillary artery. Excluding the wounds, there were 80 deligations for aneurism, with 29 deaths, or a mortality of 36.25 per cent., which corresponds very closely with the results obtained by Parker. Of the 80 cases, 9 were examples of diffused aneurism, with 5 deaths, and 71 examples of circumscribed aneurism, of which 24 died. Wyeth's tables embrace 75 cases in which the subclavian was tied in its third course on account of axillary aneurism with 47 recoveries, or a death-rate of 37 per cent., in which secondary hemorrhage played a conspicuous part. To these cases may be added a successful one recently reported by Harrison, of Liverpool.

In three of the cases mentioned in my paper, the subclavian was secured on the tracheal side of the tumor, and all proved fatal. In one of the cases, that of Mr. Colles, the ligature was not tightened till the fourth day after the operation, owing to the supervention of excessive dyspnœa and cardiac oppression.

In my own case, a traumatic one, the tumor burst at the end of the twenty-sixth day after the operation, discharging its contents into the right thoracic cavity, and thus causing fatal pleuritis. The patient, a man thirty-six years of age, was suddenly seized with intense pain in the chest, which was particularly severe at the base of the right lung, from which it extended over towards the sternum, on the one hand, and up towards the axilla, on the other. The respiration was hurried, laborious, and fifty-six in the minute ; and the pulse, which was quick and tense, rose rapidly to one hundred and forty. Two days after the accident, the patient experienced a sensation near the upper part of the chest, as if a fluid were passing from the pleural cavity into that of the aneurismal sac, and, on carefully auscultating the spot, a splashing sound could be distinctly heard at every inspiration, the noise resembling that produced by shaking water in a closed vessel. The respiration in the right lung was now bronchial, and there was extensive dulness on percussion of that side of the chest. It is proper to add that the tumor prior to the operation was about the volume of a large fist, and that the ligature, which had been placed on the artery on the external side of the scalene muscle, came away on the fourteenth day. The dissection revealed the following facts, the arteries having previously been injected.

The wound made in the operation was completely cicatrized, and the pectoral muscles, although somewhat attenuated, retained their natural appearance. The subclavian artery terminated abruptly at the outer margin of the scalene muscle, where the ligature had been applied, its caliber being closed by a mass of solid fibrin, about one-third of an inch in length, which adhered firmly to the lining membrane, and thus afforded an effectual barrier to the passage of the blood. Between this and the thyroid axis the vessel was occupied by a dark coagulum of blood, which, as it was unadherent, was probably formed only a short time before death. Beyond the seat of the ligature the artery had a rough, ragged appearance, and was sufficiently pervious to admit of the ready passage of a small probe into the aneurismal sac. Superiorly the tumor was overlapped by the brachial plexus of nerves, while in front, at its lower part, was the subclavian vein, which, besides being thrown out of its natural course, was considerably diminished in size. No pus was anywhere discoverable, the parts immediately involved in the operation being intimately consolidated by plastic matter. The aneurismal tumor, placed immediately below the clavicle, was of a conical form, and about the volume of a moderate-sized orange, being two inches and a quarter in diameter at its base. Its walls varied in thickness at different points from half a line to the eighth of an inch, and its interior communicated by means of an oval aperture, one inch and three-quarters in length by an inch and a half in width, with the pleural cavity ; it was situated between the first and second ribs, nearly equidistant between the sternum and spine, and was obviously the result of ulceration, induced by the pressure of the tumor. Both ribs were denuded of their periosteum immediately around the opening, and the serous membrane had a shreddy, ragged aspect. The aneurismal sac contained a few reddish clots arranged in a laminated manner, and closely adherent to its inner surface, especially at the part corresponding with the apex of the tumor.

The right thoracic cavity contained nearly three quarts of bloody-looking serum, intermixed with flakes of lymph and laminated clots, the latter of which were of a reddish-brown color, and had evidently been originally lodged in the aneurismal sac. The pleura exhibited everywhere marks of high inflammation, while the right lung was greatly reduced in volume, from the compression of the effused fluid. The left lung was considerably engorged, and at one or two points almost hepatized. The heart and pericardium were

sound. The abdominal viscera presented nothing unusual. None of the arteries were diseased.

There can be no doubt, from the manner in which this case terminated, that the ulceration which gave rise to the opening above referred to, and which finally led to the escape of a portion of the contents of the aneurismal sac, commenced prior to the deligation of the artery, having been produced by the violent pulsatory action of the tumor. Could such an accident have been foreseen, I should not have hesitaed to empty the sac to relieve the parts of pressure, objectionable as such a procedure certainly would be in ordinary cases.

An instance of a character similar to the above occurred in 1823, in the practice of Mr. Bullen, of England, and is related in the twentieth volume of the London Medical Repository. The patient was a man, thirty-six years of age, and the aneurism, which was of nearly five months' standing, also occupied the right side. Eighteen days after the operation, the tumor began to increase in size and to become painful. Very soon evidences of suppuration appeared, and at the end of a week, from six to eight ounces of bloody pus were ejected during a violent paroxysm of coughing, the sac immediately diminishing one-half in volume. A puncture being made into the swelling, five ounces of a similar fluid were discharged, to the great relief of the patient. It was now apparent that there was a cavity between the first and second ribs, near their sternal extremities, through which the matter had found its way into the lung, and which now readily admitted air from the latter organ, whenever the man coughed, at which time a little also escaped at the artificial opening. By degrees, the discharge of matter ceased, the cough grew less and less, and at the end of three months the recovery was perfect.

Dr. Thomas G. Morton, of this city, in 1866, met with a case of spontaneous aneurism of the axillary artery, in a man fifty-one years of age, in which he successfully tied the subclavian artery on the left side, between the scalene muscles, the ligature coming away on the eighteenth day. Subsequently, however, the tumor sloughed, followed, on the forty-third day, by violent and frequently recurring hemorrhage, and eventually by gangrene of the limb, necessitating amputation at the shoulder-joint. Notwithstanding these untoward occurrences, the patient made an excellent recovery.

Mr. Erichsen, struck with the extraordinary mortality after ligation of the subclavian artery, in the third part of its course, for spontaneous aneurism in the axilla, determined, if possible, to ascertain the cause of death. For this purpose he analyzed 48 cases of the operation, of which 23 recovered, and 25 were fatal. Of the latter, 10 perished from inflammation within the chest, 6 of suppuration of the sac, 3 of hemorrhage, 1 of gangrene of the hand and arm, 1 of suppurative phlebitis, and 1 of general gangrene, the cause of death in 3 not being mentioned.

The ten cases in the first category died of pneumonia, or of this disease and of inflammation of the pleura and pericardium, produced, as Mr. Erichsen suggests, either by an extension of the inflammation of the deep connective tissue of the neck to the contents of the chest, by the inward pressure of the aneurismal sac, or, lastly, by the injury inflicted during the operation upon the phrenic nerve.

Suppuration of the sac was the immediate cause of death in six cases, and it occurred also in two of the cases that died of inflammation of the chest. Besides these fatal cases there were six of recovery, making thus an aggregate of 14 cases, or a ratio of nearly one in three. The period at which the suppuration set in varied, on an average, from eight days to four weeks.

Hemorrhage proved fatal in three of the cases, and appeared to be a frequent cause of death after suppuration of the sac. It may proceed from the distal orifice of the artery opening into the sac, or from one of the large branches in its immediate vicinity, as the subscapular or posterior circumflex.

Gangrene of the hand and arm was the cause of death in one instance only, although the disease occurred also in two others. In Blizard's case, in which there was sloughing of the sac and pericarditis, the gangrene was confined to two fingers; while in Brodie's case it occurred both in the upper and lower extremities, thus showing that it depended, not upon a want of power in the collateral circulation, as in the other examples, but upon some peculiar state of the constitution.

Ligation of the axillary artery below the clavicle has been practised in 21 cases, with 8 deaths, or a mortality of 38 per cent. Not only is the ratio of deaths slightly greater than that of ligation of the third portion of the subclavian, but the operation is not so safe as the latter procedure, especially in cases of spontaneous aneurism, as the artery is liable to be diseased, thereby enhancing the risks of hemorrhage upon the separation of the thread.

Arterio-venous aneurism of the axillary artery has been observed in two cases by Lar-

rey, as the result of sabre-thrust, and by Dupuytren, Wattman, Legouest, and others, in consequence of gunshot injury. The case of Wattman occurred in 1843, in a man, sixty-two years of age, in whom the subclavian artery was ligated in the third portion of its course. A fatal termination ensued in the third week, from hemorrhage. In the other instances, surgical interference was not deemed either necessary or advisable.

ANEURISM OF THE BRACHIAL ARTERY AND ITS BRANCHES.

Spontaneous aneurism of the brachial artery and of its terminal branches, the radial and ulnar, is extremely uncommon, for the reason, adverted to in a previous section, that ossification and fatty degeneration of the coats of these vessels are of such great rarity compared with the same lesions of the femoral and its principal divisions. Of fourteen cases of spontaneous aneurism of the brachial artery, including one of his own, analyzed by Dr. L. E. Holt, of New York, in the American Journal of the Medical Sciences, for April, 1882, the tumor was seated at the bend of the elbow in six, in the lower third of the vessel in two, the middle third in two, at the junction of the middle with the upper third in one, and in the upper third in three. Of the thirteen which underwent treatment two recovered and one failed after instrumental compression; one was cured by combined mechanical pressure and flexion; one recovered after digital compression; and the remainder were cured by ligation of the brachial in four, the axillary in three, and tying the artery above and below the tumor in one. Ligature of the axillary was followed by secondary hemorrhage in two instances, and by suppuration and excision of the sac in the third case. Spontaneous aneurism of the ulnar and radial arteries is spoken of by several writers, but in so vague a manner as to render it difficult to determine whether the disease depended upon degeneration of the coats of the vessels, or merely upon laceration by external injury.

All these arteries are subject to traumatic aneurism; the brachial, however, is much more frequently involved than the radial and ulnar, and one of the most common causes of the occurrence is venesection at the bend of the arm, the puncture of the lancet establishing a communication between the vein and the artery, thus giving rise to what is called an arterio-venous aneurism. Or, instead of this, the instrument may almost completely sever the artery, and so induce a diffused aneurism, not opening into the vein, but sending its contents, up and down, over a large portion of the inner and fore part of the limb. Some of these latter cases are occasionally very formidable, requiring great judgment and skill for their successful management. A good illustration of the traumatic form of aneurism of the brachial artery is afforded in fig. 341.

An *arterio-venous aneurism* at the bend of the arm may sometimes be cured by systematic compression of the brachial artery, at a distance of five or six inches from the seat of the disease; but, in general, the most expeditious plan is to lay open the sac, turn out its contents, and tie the artery above and below, the inferior ligature being necessary to prevent hemorrhage from the recurrent branches.

Fig. 341.

Traumatic Aneurism of the Brachial Artery.

In extensive extravasation of blood, constituting what is usually, but improperly, called a *diffused aneurism*, the brachial artery must be exposed at the site of injury, and ligated at its cardiac and distal extremities. Compression is commonly useless.

Aneurisms of the ulnar and radial arteries must be managed upon the same general principles as those of the brachial artery. Compression can rarely be rendered available, except at the wrist, and even here it will usually be found to be unsatisfactory, on account of the difficulty of maintaining it in a firm and steady manner. Hence, the proper way is always to ligate the affected vessel at once, not waiting until the parts have become obscured by the extravasated blood. As both arteries are very deep-seated in the upper and middle portions of their extent, rendering it very difficult to expose them, it has been proposed, when they are wounded in these situations, to ligate the brachial; but the objection to this procedure is that, while the cardiac extremity of the affected vessel will thus be closed, the distal one will remain patent, and thus admit of a continuance of the hemorrhage by the recurrent circulation.

A case of aneurism of the lower part of the radial artery, caused by a rupture of this vessel in an effort which the patient made to raise himself in bed upon his hands, has been recorded by Sir Astley

Cooper. It was promptly cured by the application of two ligatures. In a case in the practice of Langenbeck, a cure was effected in twenty-four hours by a single subcutaneous injection of ergotin.

The symptoms of aneurism of the radial artery at the wrist are sometimes singularly simulated by the existence of a synovial cyst or ganglion, immediately under the vessel, within the sphere of its pulsation. Not less than five or six cases of this kind have occurred in my practice, most of them in young females in the higher walks of life. The tumor varies in size from a marrowfat pea to that of a hazelnut, and is remarkably dense and firm, with a slight degree of elasticity. The artery, stretched across it like a tense cord, beats with great vigor, and imparts to the finger of the surgeon the sensation precisely of an aneurism. The deception will be much increased if, in addition to this sensation, there is considerable pain in the part, with a feeling of stiffness in the joint. The diagnosis is determined by placing the hand in a state of forced flexion, which, by removing the tension from the tumor, either arrests the pulsation in the vessel, or changes its relation in such a manner as to lead at once to the detection of the true nature of the affection.

Mr. Pilcher met with an instance of aneurism under the ball of the right thumb in a goldsmith, from the repeated, although slight, blows inflicted with his hammer in the exercise of his trade. The disease speedily disappeared after ligation of the radial and ulnar arteries at the wrist. In a case in the practice of Mr. Syme, in a man who had, at the root of the thumb, a tumor about the size of a flattened gooseberry, all pulsation had ceased at the end of twenty-four hours under the pressure of a small spring truss applied to the vessel at the wrist. Guattani describes a case of aneurism of the muscular eminence of the thumb in a man, forty-five years old, which he cured by direct compression after it had been freely opened by a longitudinal incision. The tumor was of the size of a common apple, circumscribed, tense, indolent, and unattended with pulsation.

ANEURISM OF THE ABDOMINAL AORTA.

Aneurism of the ventral aorta is much more frequent in men than in women, and is met with chiefly between the ages of thirty and fifty. In an instance recorded by Mr. Armitage the disease occurred at the age of seven years and a half, the tumor being situated at the bifurcation of the vessel, and death being caused by the rupture of the sac. The disease, which is much less common than aneurism of the thoracic aorta, generally begins near the cœliac axis, in the form of a sac-like expansion, connected with the antero-lateral aspect of the vessel, and communicating with it by a rounded opening, from the size of a quill to that of a finger. The volume of the tumor is variable; in some cases it may not exceed an orange, while in others it may equal an adult's head. Its contents, at first fluid, soon become solidified, and arrange themselves in the form of concentric lamellæ, the number and firmness of which are often very remarkable. The sac usually inclines a little to one side, generally to the left, as there is less resistance in that direction than in the other; and, as it increases, it seriously encroaches upon the abdominal viscera, and even upon the diaphragm, especially when it is of large bulk or situated high up. The immediate cause of the disease is commonly the fatty, fibrous, or calcareous degeneration of the artery.

The symptoms of aneurism of the ventral aorta resemble, in general terms, those of aneurism of the thoracic. The pulsation, however, is usually more distinct, while the functional distress is less, owing to the more yielding character of the abdominal viscera, and the fact that they are not so important to life. The tumor, which is immovably fixed, is dull on percussion, especially in the flaccid condition of the bowels, and gradually increases in size and solidity with its age. The pain, at first slight, often becomes very severe, and usually darts about in different directions. It is generally most violent in the course of the solar, cœliac, and hypogastric plexuses, and occasionally assumes a decidedly neuralgic character. When the vertebræ are eroded, the pain is of a boring nature, more fixed, and attended with a greater amount of sympathetic disturbance. Dyspeptic symptoms are frequently present; and respiratory embarrassment invariably exists whenever the aneurism seriously encroaches upon the diaphragm.

The diagnosis of ventral aneurism is sometimes very difficult. The most reliable considerations are derived from the history of the case, the sudden nature of the attack, the existence of a pulsating and gradually enlarging tumor, with a distinct bellows sound heard over the inferior dorsal, or the upper lumbar, vertebræ, and the great pain, which is experienced in the situation of the disease, both in front and in the back, in the latter of

which it is never absent. The affections with which the malady is most liable to be confounded are, abnormal pulsations of the ventral aorta, whether arising from anemia, neuralgia, or inflammation of its coats; hydatids of the liver; enlargement of the pancreas; carcinomatous and other tumors of the omentum, stomach, colon, mesentery, or ovary; intestinal concretions; indurated feces; and abscesses of the walls of the abdomen. In order to render the examination perfectly satisfactory, the bowels should be well emptied

Fig. 342.
Aneurism of the Aorta, inducing Caries of the Vertebræ, and fatal Compression of the Spinal Cord.

as a preliminary step, when the patient should be placed in the horizontal position, with the abdomen raised somewhat higher than the chest. In this way the tumor will not only become more conspicuous, but the blood will rush into it with greater force, and thus produce more active pulsation and bellows sound. A case has been recorded by T. Spencer Wells in which a large aneurism of the lower part of the aorta was tapped through the vagina, on the supposition that it was a pelvic abscess.

Although a case of spontaneous cure of an aneurism of the abdominal aorta is occasionally met with, the prognosis is extremely unfavorable. The disease almost invariably proves fatal, death occurring either from sheer exhaustion, or from rupture of the sac behind the peritoneum, or into the peritoneum, the intestine, bladder, chest, kidney, or inferior vena cava. The period at which this event takes place varies from a few months to several years. In the case from which the annexed cut, fig. 342, from Jones and Sieveking, was taken, the aneurism produced fatal compression of the spinal cord.

It may be stated as an interesting fact, not without practical significance, that in every case of spontaneous cure of aneurism of the aorta that has ever been reported the patient was in a wasted and exhausted condition, equivalent to that produced by the treatment of Valsalva.

The *treatment* in most cases is mainly palliative, our chief dependence being placed upon rest, a properly regulated diet, and anodynes, in union with aconite, ergot, and acetate of lead. If the patient is plethoric, blood may occasionally be taken from the arm, to moderate the force of the circulation and to subdue pain.

When the aneurism is situated some distance below the diaphragm, and is not very large, experience recently furnished shows that the case may yield to rapid and persistent compression under chloroform, a method successfully practised by Murray, of Newcastle-on-Tyne, in 1864, upon a man twenty-six years of age. A tourniquet was applied above the tumor, and pressure kept up for two hours, but without any perceptible change. Three days afterwards the pressure was renewed, with the result, at the end of five hours, of the perfect consolidation of the swelling, followed by so rapid a cure that the patient was soon able to resume his occupation as a laborer. He survived the operation six years, when he died from the effects of another aneurism of the aorta situated too high up for compression. The dissection showed that the circulation within the abdomen, after the cure of the tumor, had been carried on between the middle colic of the superior mesenteric and the left colic of the inferior mesenteric arteries, including the sigmoid and hemorrhoidal branches, between the upper and ilio-lumbar, and between the inferior lumbar and circumflex iliac arteries. The arteries concerned in maintaining the collateral circulation on the outside of the abdomen were the internal mammary and deep epigastric, the hepatic and a branch of the epigastric, and the intercostal and the two epigastric, with the superficial and circumflex iliac. The superior mesenteric artery was as large as the aorta.

The operation of Murray has also been successfully practised by Moxon and Durham, Greenhow, and Philipson. It has, however, failed in the hands of Mr. Pollock, and proved fatal in the cases of Sir James Paget, and Durham, the causes of death having been peritonitis and abscess in the mesentery, and bruising of the pancreas. In two cases the pad of the tourniquet was applied on the distal side of the aneurism. In that of Skerritt, the patient died from rupture of the sac, and the case of Marshall was a failure. In the case of Bryant, which was also one of distal compression, the aneurism after death

proved to have been connected with the cœliac axis.   It thus appears, that, of 9 cases of proximal or distal compression for aneurism of the abdominal aorta, 4 were cured, 2 failed, and 3 died; results which are so brilliant and creditable as to render the procedure one of the established usages of surgery in a class of cases formerly regarded as utterly hopeless.   Ligation of the aorta for the cure of its own aneurisms must always necessarily be fatal.

Sir William Fergusson, in a case of aneurism of the abdominal aorta, tied the femoral artery, but, with the exception of a diminution of pulsation for a single day, no effect was produced on the disease.

Electrolysis has occasionally been tried in the treatment of aneurism of the abdominal aorta; but, beyond an apparently trifling amelioration, with no ulterior benefit.   Indeed, it is questionable whether, as a rule, the remedy does not do more harm than good.

The aorta may be the seat of *varicose aneurism*, caused by a communication with the vena cava by ulceration or external injury.   The occurrence is uncommon.   The tumor is of variable size and shape, compressible, especially in its earlier stages, and readily detectable by the finger.   The pulsation is generally less distinct than in ordinary aneurism, and there is occasionally a loud whizzing noise heard both by the patient and the attendants.   In a case of varicose aneurism of the aorta and left common iliac vein, under the care of Mr. Simon, compression of the former vessel terminated fatally from gangrene of the intestine.

ANEURISM OF THE BRANCHES OF THE ABDOMINAL AORTA.

Aneurism of these vessels has been observed in a few rare instances, the order of its occurrence being the superior mesenteric, the splenic, the hepatic, the cœliac axis, and the renal.   The subject is of interest chiefly in a diagnostic point of view.   In a case of aneurism of the left gastro-epiploic artery, recorded by Dr. Allé, death was caused by the rupture of the sac, from inordinate exertion in dancing.   The patient was a young woman, in the fifth month of her pregnancy, and the abdomen was filled with blood, partly fluid, partly coagulated.

In aneurism of all these vessels, except the hepatic, the renal, and the cœliac axis, the tumor is always movable, changing with the patient's position, circumscribed, more or less globular, and accompanied by pulsation as it is pushed from side to side.   In an interesting case of aneurism of the hepatic artery, recorded by Dr. Stokes, the sac was bound down by the capsule of Glisson, and lay in close contact with the biliary ducts, which were remarkably dilated throughout the liver, forming tortuous projections on its peritoneal surface.

Besides the pulsation which is always present in aneurism of these arteries, the pressure of the tumor upon the liver and gall-bladder not unfrequently causes jaundice, while its pressure upon the pancreas occasions imperfect duodenal digestion, as indicated by the pain, flatulence, acid eructations, and vomiting some time after taking food.   In a number of the recorded cases troublesome hematemesis existed.

In two cases of aneurism of the trunk of the superior mesenteric artery observed by J. Arthur Wilson, of London, the most prominent symptom in one was jaundice, in the other vomiting of blood.   Both patients complained of severe and constant pain in the middle of the back, between the shoulders.

The great uncertainty in the diagnosis of aneurism of these vessels teaches the necessity of the most careful examination in all cases of doubt, not only with the eye and finger, but the ear.   The detection of various sounds, as the bellows, sawing, or purring, in connection with the existence of a movable tumor, could not fail to throw important light upon the nature of the complaint, and thus protect the patient from the employment of harsh and useless remedies.

ANEURISM OF THE COMMON ILIAC ARTERY.

The history of aneurism of this vessel remains to be developed.   Nothing short, in fact, of a careful analysis of the various recorded cases of it can place it in its true light. That the disease is extremely uncommon in its occurrence is a circumstance which has long been familiar to surgeons.   The table of Mr. Crisp supplies only two cases of aneurism of this artery in 551 cases of the lesion, as it shows itself in different portions of the arterial system.   Both occurred in males.   In one, the tumor was seated on the right side; the patient was a sailor, exposed to hard labor in whale-fishing; the aorta was tied by Dr. Murray, of the Cape of Good Hope, but the man died twenty-three

hours after the operation. In the other case, the aneurism, also seated on the right side, was of a fusiform shape, and communicated with the common iliac vein. No operation was performed.

Varicose aneurism of the common iliac artery is very uncommon. Only a few well-authenticated cases of it are upon record. Of these, one of the most interesting is that observed by Mr. Adams, of Dublin, which seems to have been of spontaneous origin. The patient, who expired one day within a few hours after having taken a walk, had labored for several years under a tumor at the lower part of the abdomen, accompanied with severe pain and throbbing. The dissection revealed a fusiform dilatation of the primitive iliac, with an opening, at one side, of the diameter of a goose-quill, with which it communicated with the corresponding vein.

In a case observed by Leflaive, in a man, twenty-two years of age, the aneurism was caused by the thrust of a knife into the abdomen, a little below the umbilicus, towards the right side. The accident was followed by excessive swelling of the lower extremities, especially the left, by great enlargement of the veins, and, finally, by the formation of numerous troublesome ulcers, from the effects of which the man eventually perished. A tumor, extending nearly as high up as the bifurcation of the aorta, existed between the primitive iliac artery and vein; its walls were ossified, and its cavity was partially filled with fibrinous concretions. The artery bore evidence of former injury.

ANEURISM OF THE EXTERNAL ILIAC.

Aneurism of the external iliac is a rare affection. In the table of Mr. Crisp, the most elaborate hitherto furnished, it occurs only 9 times in 551 cases, while the femoral is mentioned 66 times, and the popliteal 137 times. In 364 specimens of aneurism, contained in the London museums, the same writer found the external iliac affected in 7 cases, the femoral in 12, and the popliteal in 50. The nine cases analyzed by Mr. Crisp all occurred in males: two between twenty and thirty, four between thirty and forty, one at forty, and one at fifty-six, the age of the other not being given. The disease is most common in hard working persons. One of the worst cases of it that I have ever seen occurred in a priest.

The tumor in this disease may be seated in any part of the artery, but, in general, it will be found rather low down, and, as it progresses, it manifests a tendency to pass underneath Poupart's ligament into the upper part of the thigh. It usually rapidly augments in size, and is capable of attaining a large bulk, encroaching upon the iliac fossa and the pelvic cavity, lifting up the peritoneum, and pressing forward the structures in the inguino-femoral region, so as to give rise to great deformity in this situation. The pulsation, thrill, and bellows sound are usually very distinct. If the patient is very thin, compression of the abdominal aorta will arrest the movements of the tumor, and diminish its volume, thus serving to distinguish it from other affections. The diagnosis is, nevertheless, not always so easy as might at first appear. Several cases have been reported where the common iliac artery was ligated on account of morbid growths, supposed to be aneurismal, which afterwards proved to be of a malignant character. On the other hand, a tumor really aneurismal has occasionally been confounded with one altogether of a different character. Such a mistake is most likely to happen when the aneurism is partially solidified by coagulation of its contents, thereby preventing the perception of pulsation. It is only necessary to allude to the possibility of such an occurrence in order to put the practitioner upon his guard in his investigations.

When an aneurism of the external iliac artery has attained a considerable bulk, the patient walks with extreme difficulty, and is unable to flex the thigh upon the pelvis. The whole limb is enlarged and œdematous from obstruction to the return of the venous blood, while the pressure of the tumor upon the femoral nerve keeps up constant pain, with a sense of numbness and stiffness in the parts below, generally extending as far down as the foot and toes.

Aneurism of the external iliac artery, left to itself, proves fatal in one of three ways, by rupture and hemorrhage, gangrene of the sac or limb, or constitutional irritation. Occasionally a spontaneous cure occurs.

Varicose aneurism of the external iliac artery, an exceedingly uncommon affection, may be caused, as the same disease elsewhere, by ulceration or external injury, as a stab, puncture, or gunshot wound. The symptoms present nothing peculiar. The most important, perhaps, is the extraordinary purring, whizzing, or whirring sound which the blood makes as it rushes from the diseased vessels into the intervening sac. The tumor is capable of acquiring a large bulk, and it is impossible always to distinguish it satisfactorily

from an ordinary aneurism. If compression fails, as it will be likely to do, the only resource is ligation of the common iliac, as in the interesting case of Professor Hargave, of Dublin. Although the patient, a soldier, forty-three years old, died on the seventy-third day, the operation, so far as the artery was concerned, was perfectly successful, the ligature having come away nearly a month and a half previously without a drop of blood. The immediate cause of the disastrous result was an enormous abscess of the pelvis, attended with hemorrhage.

ANEURISM OF THE INTERNAL ILIAC AND ITS BRANCHES.

Aneurism of the internal iliac, gluteal, and sciatic arteries is very uncommon, and its history has not been studied with sufficient care to enable us to present anything like a satisfactory account of it. Owing to the deep situation of the former of these vessels, the diagnosis of aneurism occupying its course would necessarily be attended with considerable difficulty, and should not be declared without a good deal of reserve and circumspection. Perhaps the best way of arriving at a satisfactory conclusion, is by the rectal exploration, as originally suggested by Professor Henry B. Sands, of New York. Indeed, in no case of suspected pelvic aneurism, should this mode of examination be neglected or overlooked. Aneurism of the sciatic and gluteal arteries is more frequently traumatic than spontaneous. In fat, muscular subjects the disease is generally difficult of recognition, and hence it is not surprising that solid growths have sometimes been mistaken for it. Mr. Guthrie and Dr. Morton each tied the internal iliac artery for a tumor which had been taken to be aneurismal, but which, after death, was found to be of a sarcomatous character, the deception having been caused by the circumstance of the tumor having received a distinct impulse from the artery. I have not met with aneurism of the pudic artery, and am not aware that the disease has ever been observed in this country. Mr. Erichsen states that the only instance of the kind with which he is acquainted is exhibited in a preparation in the Museum of the College of Surgeons at London.

Dr. George Fischer, of Hanover, has collected thirty-five cases of traumatic and spontaneous aneurisms of the gluteal and sciatic arteries, of which three-fourths affected the former vessel. They may be distinguished from each other by their seat, those of the gluteal artery being generally situated at the upper border of the great sciatic notch, while aneurisms of the sciatic artery are situated nearer to the tuberosity of the ischium, from which they extend towards the thigh or reach into the pelvis. Laying open the sac and ligaturing both ends of the divided vessel have been employed in six instances of traumatic gluteal aneurism, with four recoveries, one failure, and one death from hemorrhage. In the spontaneous and traumatic aneurisms, ligation of the internal iliac has been performed in thirteen cases, with six recoveries and six deaths, the result in one being uncertain, and ligature of the common iliac in three instances, all of which died. Galvano-puncture was tried in one case, but without benefit, while the injection of perchloride of iron was followed by four recoveries and two deaths.

Aneurism of the gluteal and sciatic arteries may be treated by ligating the internal iliac, by rectal compression, or exposing the sac by a free incision, turning out its contents, and tying the vessel above and below. Such a procedure would, unquestionably, be very bloody, but far less hazardous in the end than the deligation of the internal iliac.

The gluteal artery has been tied at least twice in this country for the cure of aneurism; once by Dr. Davidge, of Baltimore, and once by Dr. George McClellan. The tumors being of great bulk, the incisions were obliged to be unusually large, and the loss of blood was very profuse. Notwithstanding this, however, both patients made an excellent recovery. Professor Campbell, of Montreal, has successfully ligated the gluteal artery for a traumatic aneurism of that vessel. Sappey, of Paris, and Dr. Dugas, of Georgia, have tied the sciatic artery for aneurism. The case of the former was not cured, although the patient recovered; while the case of the latter terminated fatally four days after ligation of the common iliac artery for secondary hemorrhage.

TREATMENT OF ILIAC ANEURISMS.

In the treatment of aneurism of the common and external iliac arteries, compression should always be resorted to before operative interference is instituted. If it be possible, the pad of Pancoast's tourniquet should be applied to the common iliac trunk, but as this is more difficult of execution than compressing the abdominal aorta, the latter vessel is to be preferred. Of 11 cases treated by this measure, 8 were cured, and 3 were failures. In the cases of Heath and Murray, consolidation of the contents of the sac was effected.

respectively, in twenty and forty-five minutes. The patient of Professor Agnew was cured by maintaining the compression under ether for two hours on one day, and for half an hour, without an anæsthetic, on the following day.

Cases of Iliac Aneurism, treated by Ligation of the Abdominal Aorta.

No.	Operator.	Date.	Sex.	Age.	Result.	Remarks.
1	Cooper	1817	M.	38	Died in 40 hours	The operation was performed for aneurism of the left iliac artery. The tumor was of enormous size, and extended four inches above and four inches below Poupart's ligament ; the thread was applied three-quarters of an inch above the bifurcation of the aorta. The sac contained an immense quantity of clotted blood.
2	James	1829	M.	44	Died in 3½ hours	There was an external iliac aneurism, for which the femoral was ligated. Increasing in size, 33 days afterwards the aorta was tied. The ligature was applied eleven lines above the bifurcation of the vessel, and five below the mesenteric artery.
3	Murray	1834	M.	33	Died in 23 hours	There was an extensive aneurism of the right external iliac, the tumor reaching as high as the umbilicus, and more than half-way across the lower part of the abdomen. Mortification of the limb was rapidly approaching when the operation was performed. The aorta was tied about four lines above its bifurcation.
4	Monteiro	1842	M.	31	Died in 10 days	A large tumor occupied the lower part of the abdomen and upper part of the thigh. It was a spurious aneurism of the femoral artery, caused by the bursting of that vessel. The patient died, at the expiration of ten days, of secondary hemorrhage, from a small opening in the vessel corresponding with the knot of the ligature, which had been applied four lines above the point of bifurcation.
5	South	1856	M.	28	Died in 43 hours	The aneurism occupied the external and common iliac, and was of immense size. The ligature was applied a little above the bifurcation of the aorta.
6	McGuire	1868	M.	30	Died in 11 hours	The operation was undertaken with the view of tying the common iliac, but after it was begun it was found that the aneurism involved the external iliac on one side, both common iliacs, and the lower extremity of the aorta. The sac burt during the operation, without much hemorrhage, and a ligature was hastily cast around the aorta at the origin of the inferior mesenteric artery, the cord, as was found after death, including the left ureter.
7	P. H. Watson	1869	M.	...	Died in 65 hours	Secondary hemorrhage after ligature of the common iliac nine weeks before ; cut through the mesentery, and at the same time secured the external and internal iliac branches of the same side, to prevent recurrent bleeding ; did well for two days ; no further hemorrhage ; limbs regained their temperature after operation, but it sank 6° in the affected leg prior to death.
8	W. Stokes	1869	M.	50	Died in 12 hours	Aneurism involved the right common iliac, the external iliac, and femoral arteries. Pulsation returned in the sound femoral artery in nine hours.

Digital compression has been tried in several cases of ilio-femoral aneurism, but only in one successfully—a patient of Dr. Nichols, of New Orleans—after an effort of thirty hours. In a similar instance, in charge of Dr. R. J. Levis, a cure was effected with the aid of ether in less than six hours by mechanical compression applied to the external iliac. In a former edition of this work I expressed the opinion that an aneurism of the external iliac might generally be promptly obliterated, especially in its earlier stages, by compression of that vessel as it passes over the brim of the pelvis ; and Dr. T. R. Varick, of Jersey City, acting upon the suggestion, in June, 1880, employed it successfully in a case of inguinal aneurism in a man forty-eight years of age. The pressure was applied with a Ricord's bubo compressor over the ramus of the pubes, and was kept up for forty-eight hours, a small slough following the operation. This mode of treatment is certainly

entitled to a fair trial.   Digital compression would, I think, be preferable to any other, on account of the greater facility of its application, and the avoidance of all risk.

If compression fail, the only recourse is deligation of the artery leading to the tumor, the external iliac, when the aneurism is situated low down so as to leave a sufficiency of the vessel in a suitable condition for the reception of the ligature; or, when the reverse is the case, the common iliac; or, when the latter is implicated, the abdominal aorta.   The result of ligation of the external iliac is encouraging, since of 169 cases in which it has been tied for all causes, only 61, or 36.09 per cent. died.   Ligation of the common iliac, on the other hand, is one of the most formidable operations in surgery, 49 or 77.77 per cent. of the 63 cases in which it has been practised for various affections, having perished. The table, p. 770, indicates the results of eight cases in which the abdominal aorta has been tied for iliac aneurisms, the case of Mr. Stokes being included, although Porter's wire compressor was employed instead of an ordinary ligature.

It will be perceived from the table that the eight cases in which the abdominal aorta has been tied terminated fatally; a result which might assuredly have been foreseen by the distinguished surgeons who performed the operation.   Questionable as the propriety of such an operation is, I should, I confess, be strongly tempted to perform it if my patient were placed in circumstances precluding all hope of relief from any other source. That this was the feeling which prompted Sir Astley Cooper, in 1817, to undertake it, and which has since induced others to imitate his example, is more than probable, and our only regret is that their efforts were not crowned with success.   What the effect might have been if the cases had been of a more favorable nature prior to surgical interference is, of course, merely a matter of conjecture, but it is perfectly evident, from their history, that they were all in as desperate a condition as they could well have been at the time. The tumor, in every instance, was of enormous volume, almost, in fact, ready to burst: in Mr. Murray's patient there was, besides, incipient gangrene of the lower extremity. In the case of Mr. James, an error of diagnosis had been committed, which led, improperly, as was afterwards proved, to ligation of the femoral artery, thereby causing the patient not only much suffering but the loss of much valuable time, upwards of four weeks having elapsed between the two operations.

In performing the operation, the peritoneum was divided in three of the cases, and left intact in five; in one instance, it was opened to the extent of nearly four inches.   Such a procedure would probably of itself have been a cause of death, had the patient survived the immediate effects of the deligation of the vessel.

The case of Dr. Monteiro, the most successful of all, is replete with interest, as it establishes the fact that the circulation may go on in the lower extremities, after the flow of blood in the abdominal aorta has been completely arrested by the ligature.   The patient survived the deligation ten days, when he died of secondary hemorrhage, caused by a small aperture in the side of the vessel corresponding with the knot in the thread.   The dissection showed that the peritoneum, which had not been cut in the operation, was perfectly free from inflammation.   The aorta had been ligated four lines above its bifurcation, and an inch below the inferior mesenteric artery.   The aneurism, which was a false one, had originated in a rupture of the superior extremity of the femoral artery, from which the blood had made its way upwards, underneath Poupart's ligament, through the intermuscular connective tissue, into the iliac fossa, and thence on behind the peritoneum along the posterior part of the abdomen, as high up as the diaphragm and liver. The common and external iliac arteries were involved in the tumor, and were in an inflamed and friable condition.   The external wound had nearly healed.

It is worthy of remark that the pulsation in the tumor ceased immediately on tying the ligature, but returned slightly on the third day, and became more marked on the fourth. Hemorrhage supervened the day before death.   The operation was followed by coldness of the lower extremities, but in four hours afterwards this had passed off, and the temperature rose a little above the natural point.   No paralysis of the limbs was at any time present.

In addition to the foregoing eight cases, the aorta has been tied twice by Czerny, on account of hemorrhage.   In the first case the femoral and common iliac arteries had been previously ligated for bleeding from a gunshot wound of the thigh, and the patient died in twenty-six hours.   In the second case the operation was resorted to for the arrest of hemorrhage from a torn renal artery in removing a kidney for malignant disease, and the patient survived ten hours.

In a remarkable case of traumatic aneurism of the external iliac, in a seaman, thirty-one years of age, Mr. Syme, in 1862, laid open the sac, to the extent of six inches, turned

out a mass of blood and fibrinous clots, to the amount of six pounds, and tied the common, internal, and external iliac arteries where they communicated with the tumor. The circulation in the aorta was controlled by a compressor fastened around the abdomen. The edges of the wound were united by silver sutures, covered with dry lint, and gently supported by a bandage. Although the ligatures dropped off on the nineteenth day, the patient remained in a very precarious state until the end nearly of the third month, when so decided an improvement took place as to remove all doubt as to his ulterior recovery. A short time after this, however, he contracted a severe cold, from the effects of which he soon died. The enormous tumor, prior to this bold and brilliant operation, extended, on the one hand, from below Poupart's ligament considerably above the umbilicus, and, on the other, from nearly two inches beyond the middle of the abdomen, towards the right side, completely across the left iliac region, so as to overlap the crest of the iliac bone. Another remarkable circumstance in the case was the small amount of suppuration that followed the opening of the sac.

ANEURISM OF THE FEMORAL ARTERY.

Aneurism of the femoral artery is very common, although less so than that of the popliteal. In Mr. Crisp's cases, 551 in number, 66 relate to the femoral artery, of which 61 occurred in males, thus showing that the disease is very rare in women. The period of life at which it is most frequently met with is from thirty to fifty. As in the other arteries, aneurism of the femoral is most common in the laboring classes, particularly in those persons who are subject to severe muscular exertion of the lower extremities, causing a sudden strain upon the vessel. Instances have been observed in which each femoral artery was simultaneously affected with aneurism, and it occasionally happens that the same vessel has two such tumors connected with it.

The femoral artery is not equally subject to aneurism in all parts of its extent. The superior third suffers more frequently than the rest of the vessel, and spontaneous aneurism occurs here much oftener than in any other external artery, except the popliteal. Sailors are said to be particularly liable to the disease in this situation, owing, as Mr. Crisp supposes, to the violent flexion and extension of the thigh which they are obliged to make in mounting the rigging and performing other labor on shipboard. I have never seen an instance of spontaneous aneurism in the lower third of the thigh, and general experience concurs in declaring that such an occurrence is extremely uncommon. In some of the published cases, the disease is described as having been femoro-popliteal, a term evidently intended to convey the idea that the lesion involved both the terminal portion of the femoral and the superior portion of the popliteal.

Diagnosis.—The diagnosis of femoral aneurism, although generally easy, is sometimes involved in so much obscurity as to cause not a little perplexity. This is more especially the case when the tumor is seated along the middle or lower third of the thigh, where the artery is tightly bound down by the muscles and aponeuroses. Abscesses and various morbid growths, solid, semisolid, or fluid, and malignant and non-malignant, are the affections with which it is most liable to be confounded ; and it behooves the surgeon, in every case of doubt, to institute the most careful and thorough examination before he expresses an opinion in regard to its character, or permits himself to engage in any operative procedures for its relief. The best diagnostic, unquestionably, is the effect which compression of the femoral artery exerts upon the tumor, when it is situated some distance below Poupart's ligament, or of the ilio-femoral, when it occupies the superior part of the thigh. If the tumor is aneurismal, the compression will not only arrest its pulsation, thrill, and bellows sound, but, while it is being kept up, it will enable the surgeon to squeeze out its contents, and thus greatly diminish its volume, circumstances which cannot possibly occur when the swelling is of a non-aneurismal character, whatever may be its structure or consistence. The exploring needle is only to be used in cases not admitting of discrimination by this method, and then it should be so fine as not to cause hemorrhage or excite inflammation. It is worthy of note, in a diagnostic point of view, that the tumor in aneurism of this vessel almost invariably springs from its anterior surface.

The femoral artery, in the upper portion of its extent, is sometimes protruded forward by a *synovial burse*, situated behind the psoas muscle, just below Poupart's ligament, especially when the pouch is inflamed and much distended, in which case it will probably receive an impulse from the vessel, so as to cause the swelling to simulate aneurism. The proper way to determine the diagnosis is to flex the thigh upon the pelvis, a procedure

which, by taking off the tension of the muscles, puts a stop to the pulsation of the tumor, and thus reveals the true nature of the disease.

A number of *lymphatic glands* lie in the upper part of the thigh, immediately upon and around the femoral artery. Enlargement of these glands has been mistaken for aneurism, and, conversely, aneurism for enlargement of the glands; but the history of the case and a careful examination of the parts will generally promptly clear up the diagnosis.

Psoas abscess occasionally points below Poupart's ligament, and might be mistaken, by a careless observer, for aneurism of this vessel, or of the external iliac. The best diagnostic signs are the want of pulsation, the soft and fluctuating character of the swelling, the absence of discoloration of the skin, and our ability to efface the swelling almost entirely when the patient lies on his back with the thigh and pelvis a good deal elevated. Moreover, if there be any pus, a drop will be sure to follow the withdrawal of the exploring needle.

Progress.—The course of the aneurism is variable. When it is situated high up, it is liable, in its progress, to extend upwards, and to project at length beneath Poupart's ligament into the pelvic cavity. When, on the other hand, it involves the inferior portion of the artery, it may pass down into the ham, and so simulate popliteal aneurism. The swelling usually increases rather rapidly, and, in time, often spreads over a large space, diffusing itself, in fact, widely, in consequence of the giving way of the two inner tunics of the artery. When this is the case, the limb below the seat of the tumor becomes greatly enlarged and œdematous, from obstruction to the return of the venous blood, and the patient constantly complains of stiffness, pain, and numbness in it, extending generally as low down as the feet and toes. In the more advanced stages of the disease, progression becomes difficult and finally impracticable, the whole limb feeling like a dead, heavy mass. A spontaneous cure occasionally occurs, as in a case from which the adjoining cut, fig. 343, was taken; but most commonly the disease goes on from bad to worse, until life is destroyed by gangrene, excessive suppuration, hemorrhage, or constitutional irritation.

Fig. 343.

Spontaneous Cure of an Aneurism of the Femoral Artery by the Sac being filled with Coagulum; the Vessel remaining pervious.

Treatment.—The treatment of aneurism of the superficial femoral artery may, I think, generally be successfully conducted by compression, especially now that our means of applying and regulating it are so much better understood than formerly. The compression may be made either with the finger or by means of one of the numerous mechanical contrivances before the profession. In the case of a negress, aged thirty-two, who was under the joint care of Dr. S. W. Gross and myself, in 1859, on account of a large aneurism of the upper third of the femoral artery, the assistants succeeded in effecting complete solidification of the contents of the sac in forty-six hours, by digital compression alone. The tumor progressed most favorably, and in less than three weeks after the operation the woman was able to walk about the house. In this case, referred to in a previous section, there was not more than an inch of space between the aneurismal sac and Poupart's ligament, in consequence of which the compression was obliged to be applied to the iliac artery as it passed over the brim of the pelvis. Several instances of an equally gratifying termination have followed this treatment in the hands of other surgeons. In a case of aneurism of the femoral artery, the size of a small orange, six inches below Poupart's ligament, in a man seventy-eight years old, under the charge of Mr. F. R. P. Drake, of England, in 1873, a rapid cure followed digital compression maintained for ninety minutes.

In a case of aneurism of the upper portion of the femoral artery, in a man thirty-eight years of age, under the charge of Dr. Buckminster Brown, of Boston, in 1863, a cure was effected by direct compression of the tumor by means of a pad, accurately fitted to the swelling, and secured around the pelvis by a belt, the degree of pressure being regulated most of the time by two cannon balls, one of twelve and the other of twenty-four pounds, each applied on every alternate day. The patient was confined to his back for ten months,

and retained under surveillance upwards of six months longer. The tumor extended as high up as the brim of the pelvis, and was three inches and a half in diameter. Full particulars of the case are given in the Boston Medical and Surgical Journal for March, 1866.

Several instances of aneurism of the femoral artery cured by flexion of the thigh upon the pelvis have lately been reported, one, among others, by Dr. Buck, of New York, and the treatment is well worthy of further trial, especially in cases of recent standing and of small size.

When compression and flexion are inapplicable, the only resource, of course, is deligation of the artery which supplies the tumor with blood. The operation is easily done at Scarpa's triangle when the aneurism occupies the middle or lower third of the femoral artery, or even when it extends up to the inferior portion of this space, provided the coats of the vessel are sufficiently sound to bear the pressure of the ligature. When this is not the case, or when the tumor is situated high up, near Poupart's ligament, or projects beneath it partly into the pelvic cavity, the remedy usually adopted is ligation of the external iliac, an operation which, although not devoid of risk, has now been performed so often and so successfully as to be justly ranked among the established resources of surgery.

Ligation of the external iliac is generally regarded as a much safer operation than ligation of the common femoral. Of 12 cases referred to by Mr. Erichsen, in which the latter vessel was secured, under such circumstances, secondary hemorrhage occurred in 9, of which 3 proved fatal. The causes of this disaster are usually supposed to be the great shortness of the common femoral artery, and the numerous branches that are detached from it and the external iliac, rendering it thus very difficult for a solid coagulum to form above the ligature.

These statistics are in striking contrast with those of the Dublin surgeons, who, in 8 cases of this operation, have not had a solitary death. The first operation was performed, in 1849, at the Meath Hospital, by the late Professor William H. Porter, and the next by his son, Mr. George H. Porter, in 1860. The vessel, in this situation, is quite superficial, and is easily exposed by a short horizontal incision, half an inch below Poupart's ligament. The femoral vein lies at its inner side, and is, of course, carefully avoided.

During the past five years the old operation of opening the sac, and taking up both ends of the vessel, has been successfully performed by Mr. Birkett and Mr. Cooper Forster on account of rupture of the sac, and by Mr. John Gay in a case in which the sac was perfect. In the first two instances the circulation was controlled by the abdominal tourniquet.

A number of cases of femoral aneurism have been recorded in which a cure was effected simply by refrigerant applications to the tumor, aided by steady compression with the bandage, strict recumbency, and an abstemious regimen. This treatment has occasionally succeeded both in the spontaneous and traumatic form of the disease.

A singular case of aneurism of a large anomalous artery of the thigh has been recorded by Mr. C. H. Fagge in Guy's Hospital Reports for 1864. The vessel arose from the internal iliac artery, ran down the back of the thigh, and terminated in the popliteal, as the main artery of the lower extremity.

Mortality.—In Mr. Crisp's 66 cases, above referred to, the external iliac alone was tied in 44, and in two others both this artery and the femoral ; 36 of the patients recovering and 10 dying. Of the latter, three perished from hemorrhage, four from gangrene of the sac or limb, one from tetanus, one from exhaustion, and one without any apparent cause. In 12 of the cases the femoral artery alone was tied, with a result of 9 cures to 3 deaths. Amputation was successfully employed in five cases ; in two the tumor was obliterated by compression, and in one the disease spontaneously disappeared.

In the table of Dr. Norris, comprising 118 cases of ligation of the external iliac artery, of which, however, 97 only relate to aneurism, 85 recovered, and 33 died, three of the former having undergone amputation of the limb in consequence of gangrene. In 4 of the 97 cases of aneurism the disease existed simultaneously both in the thigh and in the ham, and in 3 of these the operation succeeded in curing both tumors. A return of pulsation in the sac took place in 9 cases, and hemorrhage in 14, of which 7 proved fatal, and 7 recovered. In 10 cases the tumor suppurated after the operation, although they all ultimately did well. Gangrene of the limb occurred in 16 cases out of the 118, of which 12 died. In two instances the peritoneum was wounded, but both patients recovered. To these cases may be added 51, of which 35 were analyzed by Dr. Cutter, of Newark, and 16 are tabulated in Circular No. 6. Of the entire number, or 169, 61, or 36.09 per cent.,

died. In 126 cases, the vessel was tied for aneurism, with a result of 35 deaths, or a mortality of 27.77 per cent.

Varicose aneurism of the femoral artery and vein is occasionally observed. The accident is commonly produced by external injury, as a gunshot, knife, or sabre wound, but it may be also caused by ulceration; and Baroni has related a case in which it followed upon a contusion of the thigh. The treatment should, as a general rule, be entirely of a hygienic character, experience having proved that operative interference is usually followed by fatal results. In some of the recorded cases of this affection the patients lived for many years, in one as many as twenty, in comparative comfort.

In a case of this description, in a lad, fifteen years of age, in consequence of a stab with a knife, Professor Spence, of Edinburgh, succeeded in curing the affection by ligating the superficial femoral artery above and below the aneurism, without opening the sac. In a similar operation, in the hands of Malgaigne, the patient died from the combined effects of hemorrhage and profuse suppuration.

A very interesting case of *aneurismal varix* of these vessels was kindly brought to my Clinic at the Jefferson Medical College, in 1864, by Dr. W. B. Atkinson. The man had been wounded a year previously by a musket ball. He experienced no inconvenience whatever from the disease.

ANEURISM OF THE DEEP FEMORAL ARTERY.

Aneurism of this vessel is extremely uncommon, and I am not aware that it has ever been observed in this country. Mr. Erichsen refers to five cases, which, he says, are the only ones of which he could find any record; and Mr. Bryant has met with another case. This remarkable exemption from disease is the more surprising, when it is remembered how very liable the deep femoral artery is to calcification and atheromatous degeneration, the ordinary predisposing causes of spontaneous aneurism. Traumatic aneurism, the result of gunshot injury and fracture of the thigh-bone, is more frequent.

The symptoms of aneurism in the deep femoral artery present nothing peculiar. The pulsation is easily arrested by compression of the external iliac at the groin, and the superficial femoral is without difficulty drawn away from the tumor, so as to show its independent character. Care must be taken not to mistake the disease for a malignant growth. The sac seldom attains any great bulk. The treatment usually suggested is ligation of the external iliac; but were I to meet with such a case, I should certainly tie the common femoral, immediately below Poupart's ligament, as a far safer procedure, with a temporary ligature, removed at the end of forty-eight hours.

In a case of this disease, treated by Mr. Erichsen, in 1870, all pulsation in the aneurism, one of large size, was arrested in twenty-four hours by means, first, of Carte's compressor, and afterwards by the finger, applied to the common femoral artery. The patient, for a considerable portion of the time, was under the heavy influence of a large dose of chloral.

ANEURISM OF THE POPLITEAL ARTERY.

The extraordinary frequency of aneurism of the popliteal artery has long been familiar to pathologists and surgeons. With the exception of the thoracic portion of the aorta, there is no artery in the body which is so often the subject of this disease. The table of Mr. Crisp, already so frequently referred to, comprises an analysis of 551 cases of spontaneous aneurism, of which 137 occurred in the vessel under consideration, the thoracic aorta suffering 175 times. Three circumstances seem to serve to establish this extraordinary liability to aneurism on the part of this artery; one is its extreme proneness to ossific and fatty degeneration, another, the curve which it forms behind the knee, and the third, the sudden and forcible extension to which it is so constantly exposed in the various movements of the lower extremity. Broca ascribes the great frequency of the disease to the pressure to which the popliteal artery is subjected in the ring-like opening in the soleus muscle.

Age and Sex.—Popliteal aneurism occasionally occurs at a comparatively early age, a number of cases having been observed in which it took place before the twenty-fifth year. Mr. Syme has related one in a child of seven years. The great majority of instances, however, are met with between thirty and fifty. Both sides seem to suffer nearly in an equal degree, and both are occasionally affected simultaneously, or suc-

cessively, as I have myself witnessed in several individuals. The disease is almost peculiar to men. In Mr. Crisp's cases, 137 in number, 133 occurred in males, and only 4 in females. No occupation is exempt from aneurism of the popliteal artery, but the stastistics which have been published upon the subject conclusively show that the laboring classes, especially soldiers, sailors, bargemen, and porters, who are in the constant habit of making long-continued and violent exertions of the muscles of the lower extremities, are more liable to it than any other. The idea, first broached by Morgagni, that postillions and coachmen are particularly prone to popliteal aneurism, has been proved to be erroneous.

Diagnosis.— Aneurism of the popliteal artery is probably produced in most cases by a sudden and violent sprain or twist of this vessel while its coats are in a state of calcareous degeneration, and, consequently, deprived of their elasticity, by which they are prevented from following the various movements of the leg with their accustomed freedom, a sudden rupture being thus induced, of which the patient is himself often made conscious, either by his feeling, or by a kind of snapping noise. The tumor, being at first quite small, generally escapes attention until it has acquired a considerable bulk, as, from the great depth at which the artery is situated, and the unyielding nature of the parts in the ham, it takes some time for it to reach the level of the surrounding surface, or to exhibit to the eye the characters of a distinct swelling. A careful examination, however, will always enable us, even at an early period, to arrive at a satisfactory conclusion respecting the nature of the case, except, perhaps, in very fat subjects. The tumor will be found to throb synchronously with the artery in the groin, and, by grasping it firmly between the thumb and finger, it may readily be pushed about in the hollow between the tendons of the flexor muscles, feeling like an elastic, circumscribed knob, which is easily diminished by pressure, but immediately regains its former size when the pressure is removed. As the disease progresses, the sac increases in volume, and encroaches more and more upon the popliteal space, pushing aside the soft parts, compressing the popliteal vein and nerve, and interfering seriously with the movements of the limb. The leg is habitually bent at an obtuse angle with the thigh, and all efforts to straighten it prove abortive; it is the seat of constant aching pains, with a sense of numbness or tingling; its temperature is notably diminished, and its subcutaneous connective tissue, owing to the obstruction to the return of the venous blood, is loaded with serum, or serum and lymph, giving the surface a glossy, shining appearance, and causing it to pit under pressure. The ear and the hand readily detect the characteristic thrill and bellows sound.

Aneurism of the popliteal region is liable to be confounded with various kinds of tumors, and we read of cases in which the sac was laid open under the impression that the disease was not arterial. The lesions for which it is most apt to be mistaken are abscesses, solid and fatty growths, and synovial burses.

Abscess of the ham is of very uncommon occurrence, and is generally easily distinguished by its inflammatory character, and by the history of the case, and by the absence of pulsation, by the presence of fluctuation, especially when the matter is considerably in quantity, and by our inability to produce any change in the volume of the swelling by compression of the femoral artery high up in the thigh. When any doubt exists, a small exploring needle, carefully inserted into the tumor, will readily determine the diagnosis.

Solid growths, of various kinds, benign and malignant, are liable to form in the popliteal region, and might be mistaken for aneurism, especially by a careless and inexperienced surgeon. The fact that such tumors are usually stealthy in their origin, tardy in their development, firm in their consistence, and free from pulsation, will always readily distinguish them from aneurism of the popliteal artery.

A *synovial burse* is occasionally developed in this space, but the occurrence is rare, and it would be difficult to imagine how such a growth as this should ever be confounded with an aneurism in this region. In the Louisville Medical Review, a case of this affection is reported by Dr. S. W. Gross, in which the largest tumor of this description that I have ever seen, occurring in a man twenty-nine years of age, was readily diagnosticated by the exploring needle, although its history—especially the absence of pain and pulsation, its non-interference with the patient's occupation, and the preservation of the natural appearance of the leg below the knee—had been sufficiently denotive of its true nature without any expedient of this kind.

Progress.— Aneurism of the popliteal artery may remain circumscribed for a considerable length of time; in general, however, it soon becomes diffused, and by its pressure upon the surrounding structures causes not only great pain and swelling in the leg below

the knee, but a tendency to mortification by cutting off the nervous and vascular supplies. Such a termination, in fact, is almost inevitable if the case be permitted to proceed unchecked. Gangrene may occur at a very early stage of the disease, while the tumor is yet quite small, by its direct pressure upon the lower part of the popliteal artery, or upon its immediate offsets. Generally speaking, however, it is one of the more remote effects of the disease, as the gradual or sudden destruction of the more attenuated portion of the sac, and the escape of its contents into the neighboring tissues, rendered thus additionally tense by the unyielding aponeurosis. In this manner, an aneurism originally circumscribed, and, perhaps, quite small, may, in a few hours, become widely diffused and of enormous bulk, obscuring the pulsation both in the tumor and in the distal portion of the limb, if, indeed, not completely arresting the circulation. Similar effects often follow upon what is improperly called a diffused traumatic aneurism, in which the blood escapes more or less rapidly from the wounded vessel, and inundates the surrounding structures, frequently to a great and most injurious extent, arresting the circulation, and occasioning gangrene of, perhaps, a large portion of the limb below the seat of the compression. The foot and leg are cold, heavy, insensible, œdematous, of a speckled, glossy, or tallowy hue, and exquisitely painful. The patient, weak and feverish, soon becomes delirious, and, if relief be not promptly afforded, dies from exhaustion. Occasionally a popliteal aneurism discharges its contents into the knee-joint, where they speedily set up violent inflammation, necessitating amputation.

Sometimes a spontaneous cure occurs, probably by the pressure of the tumor upon the artery, or the detachment of a clot, thereby arresting the circulation in the sac. The late Professor Pancoast had a case of popliteal aneurism upon which he had intended to operate the next day; but when the time arrived all pulsation in the tumor had ceased, and the man gradually recovered without any further trouble.

Treatment.—The treatment of popliteal aneurism was, until recently, usually conducted by deligation of the femoral artery in the superior third of the thigh, according to the method of John Hunter, first practised in 1785. Since 1840 numerous cases have been treated by other means, more especially compression in its several forms, and so gratifying have been the results, in most instances, that the old operation is likely, before long, to become, in great measure, obsolete. Of 403 cases, analyzed by Professor Agnew, 250 were cured. Blackman effected a cure by digital compression in two hours; Holt, in sixteen hours; and Bryant, in one case, in four hours and a half, and in another, in twenty-four hours. Examples, equally remarkable, have occurred in the practice of other surgeons. On the other hand, in a case of my own, digital compression was incessantly maintained for four days and a half without any benefit whatever, a cure being afterwards readily effected by ligation of the femoral artery. Dr. James R. Wood, in 1850, published an account of two cases of popliteal aneurism successfully treated by the joint agency of mechanical and digital compression. Dr. Cheever, of Boston, effected a cure by acupressure of the femoral artery; and in a case reported by Herbert Page, of England, a similar result followed the manipulation of the sac. Mr. Henry Lee, in a case of traumatic aneurism of the ham, was also successful with acupressure.

Digital compression for the cure of popliteal aneurism is generally applied to the common femoral artery immediately below Poupart's ligament, and mechanical compression to the superficial femoral, in Scarpa's triangle. The pressure, however, may, from time to time, be shifted from one point to another, according to the tolerance of the patient, who should be freely narcotized during the whole course of the treatment.

Forced flexion, described at p. 720, is particularly applicable to aneurism of the ham, and always deserves a fair trial, if the tumor is not so large as to encroach seriously upon the structures of the joint or to threaten to discharge itself into its interior. In a case which I treated, in 1861, at the College Clinic, in a man thirty-five years of age, all pulsation in the aneurism ceased in less than twenty-four hours. The disease had come on three months previously, from a severe strain. The tumor was of an elongated, oval shape, large, circumscribed, and characterized by the ordinary phenomena. A number of examples of popliteal aneurism successfully treated by this method have occurred within the last ten years.

When compression and forced flexion fail, or when the case is not a suitable one for such procedures, the only resource is ligation of the superficial femoral artery in the lower part of Scarpa's triangle, where the vessel, although closely invested by the femoral vein, is always easily exposed, the sartorius muscle serving as a guide to the knife. The greatest possible care must be taken in separating the two vessels, as their adhesions are most intimate, and the ligature must be passed from within outwards. As a rule, it is

not advisable to perform the operation until the tumor has acquired a considerable bulk, or until there is reason to believe that the collateral circulation is sufficiently active to enable it to carry on the circulation in the distal portion of the limb after the ligation of the main trunk. The limb, placed in an easy, relaxed position, is enveloped in flannel, and, if need be, surrounded with bottles of warm water, until it has regained its normal temperature, which is often materially depressed after the operation. The feet should be carefully protected from pressure, lest gangrene arise, and everything should be done, by the avoidance of motion and officious interference, to promote the healing of the wound. The patient must not be allowed to sit up in bed, or to move the limb for some time after the detachment of the ligature, otherwise, the adhesions giving away prematurely, secondary hemorrhage might supervene. The ligature is usually detached from the tenth to the thirteenth day.

When ligation, digital and mechanical compression, and forced flexion fail to afford relief, or when, after the employment of these measures, gangrene sets in, the only resource is amputation of the thigh, performed as speedily as possible, after the supervention of the disease. A similar procedure will be required when the aneurism has burst, and sent its contents widely through the connective tissue beneath the skin and among the muscles. Obstinate secondary hemorrhage may also necessitate amputation, although, in such an event, acupressure may occasionally be successfully employed. Partial gangrene, occurring in small spots on the tumor, the leg, or the foot, does not always demand the removal of the limb, especially if the patient is otherwise in good condition.

In two remarkable cases of incipient gangrene due to the interruption of the collateral circulation by pressure of the tumor, the limb was saved, in one by Lawrence, and in the other by Benza, by cutting down upon the sac, laying it freely open, and turning out its contents, a ligature being applied to each extremity of the diseased artery. Such a procedure necessarily involves great risk, both immediate and remote; the former depending upon hemorrhage, which must always be more or less copious; and the latter upon inflammatory irritation and its consequences, as extensive suppuration, ulceration, and sloughing of the exposed structures.

Mortality.—The mortality from the operation for popliteal aneurism by the Hunterian method would seem to be variable. In the table of Dr. Norris, comprising a list of 153 cases of aneurism, for which the femoral artery was tied, 112 were cured, and 41 died. The table of Mr. Crisp furnishes 110 cases, operated upon according to the Hunterian method, of which 91 recovered completely, 7 required amputation after the use of the ligature, and 12 died. Of the 11 cases of double popliteal aneurism comprised in it, all were cured; 10 by ligature, and one by compression. The greatest cause of the mortality after the ligation of the femoral artery is gangrene of the leg.

Of 278 cases collected by Professor Agnew, 173 were perfectly cured. The remarkable freedom from danger in this operation in the hands of certain surgeons is admirably exemplified in the practice of Mr. Syme, who, up to June, 1866, had ligated the femoral artery for the cure of popliteal aneurism in 35 cases, without any bad results, except in a single one, which had previously been subjected to compression, and in which the sac suppurated without any fault of the ligature.

Amputation performed as a means of saving life, in cases of incurable popliteal aneurism, shows a very fair amount of success. There are, however, no statistics by which a comparative estimate may be formed between the results of this operation and the ligature of the femoral artery practised for the cure of this affection.

The ham is occasionally the seat of *aneurismal varix*. One of the most extraordinary cases of the kind on record is that related by Dr. Dorsey, in his " Elements of Surgery." The patient had been wounded in the upper part of the leg twelve years before, by a load of buckshot. The limb was very painful, all the veins were enormously enlarged from the toes to the groin, and incorrigible ulcers existed upon the foot and ankle. The thrill so peculiar to this species of aneurism could be distinctly perceived. The femoral artery was tied at the middle of the thigh; but the operation was followed by mortification of the leg, and during the separation of the slough, one of the enlarged veins suddenly gave way, causing copious hemorrhage, which, although it was for a time controlled by ligating the vessel, again broke out, and finally proved fatal. The femoral artery was in a dilated and unnatural condition as high as the groin, and a bougie was readily passed from the popliteal into the posterior tibial artery, and thence into a venous pouch at the inner part of the leg, below the knee.

Varicose aneurism of the ham is uncommon. Cases of it have been recorded by Larrey, Hodgson, Porter, and other observers, generally as a result of injury, as a punc-

ture or gunshot wound, but now and then as a spontaneous occurrence. The tumor may acquire a large bulk, and be accompanied by excessive dilatation of the popliteal vein. The treatment should be altogether hygienic, except when the disease is productive of great pain and inconvenience, when the sac should be laid open, and the artery tied above and below.

Traumatic aneurism, properly so called, may occur in this region from a sabre wound, a musket ball, or the sharp end of a piece of bone, as in fracture of the femur or tibia. The blood is generally widely diffused, and the diagnosis is often greatly obscured by the attendant swelling. If the symptoms are urgent, the artery should be exposed and ligated at each extremity; otherwise the case should be treated upon general principles, in the hope of gradual ulterior accommodation of the tumor, if not a spontaneous cure.

ANEURISM OF THE ARTERIES OF THE LEG AND FOOT.

Spontaneous aneurism of the arteries of the leg is very uncommon. In a paper, read before the American Surgical Association, in September, 1881, Professor R. A. Kinloch, of Charleston, analyzed 20 cases of spontaneous aneurism of the posterior tibial artery, of which 18 occurred in males, the sex being uncertain in 2. In two the supposed cause was stamping with the foot, and in one, each, pulling on a boot, a fall, standing long in one position, and overexertion, the cause being undetermined in 14. The age of the subjects ranged from nineteen to sixty-six years. The femoral artery was ligated in 12 cases, in three of which compression had previously failed, with a result of 5 cures and 7 deaths. Compression alone was employed in 5 cases, of which 3 were cured and 2 were failures. One of the cures was obtained by Esmarch's bandage. Amputation was resorted to in 5 instances, in only one of which was it the primary plan of treatment, with a result of 3 recoveries and 2 deaths; and in one case the sac was successfully laid open, and two ligatures applied.

The traumatic form of the disease is the most frequent, and there are few lesions in surgery more difficult to manage, especially when the affection involves the posterior tibial artery, owing to the great depth at which this vessel is situated, and the contused condition of the parts arising from the extravasated blood. The proper remedy, of course, is free exposure of the affected vessel, removal of the coagula, and ligation of both ends. To accomplish this to the best advantage, often involves great coolness on the part of the operator, and an unusual amount of anatomical knowledge and dexterity. During the operation, the iliac artery should be compressed at the brim of the pelvis, or a tourniquet be applied around the upper part of the thigh. Without such precaution, the hemorrhage might be frightfully profuse.

In 1873, a man thirty-five years of age, was admitted into the Jefferson Medical College Hospital, under the joint care of Professor Wallace and myself, on account of an aneurism of the posterior tibial artery, the size of a large fist, which had made its appearance eight months previously, in consequence of a wound inflicted by the sharp bony spine of the sting-ray, or trygon pastinaca. After much difficulty, owing to the confused condition of the surrounding structures, I succeeded in tying the artery above and below the tumor, which was thoroughly freed of its contents, but not removed. The man did well for the first forty-eight hours, when erysipelas and pyæmia ensued, from the effects of which he died seven days afterwards.

The annexed cut, fig. 344, affords a good illustration of an aneurism of the posterior tibial artery undergoing spontaneous cure, the sac being filled with concentric coagula. The tibial nerve is spread over the back part of the pouch.

A case of spontaneous aneurism of the dorsal artery of the foot was reported by Mr. Adams, of the London Hospital, in 1877, in a man, twenty-nine years of age. The tumor, the size of a walnut, was situated over the outer side of the astragalo-scaphoid articulation, and had come on without any assignable cause, about one month previously to the admission of the patient. The ligation of the anterior tibial artery in the upper portion of its extent, performed for the site of the disease, was followed by violent inflammation of the foot, necessitating amputation of the leg. The dissection of the parts showed that the aneurism had penetrated the astragalo-scaphoid joint. In a case under my care in 1874, in an old colored man, the aneurism, situated in front of the ankle-joint, had come on spontaneously

Fig. 344.
Aneurism of the posterior Tibial Artery, with the Nerve spread over the back part of the Pouch, which is entirely obliterated by concentric Coagula.

seven years previously, and was about the size of a pullet's egg ; the artery was tied above and below the tumor, and then dissected out, but the operation was followed by erysipelas, which ended fatally a few days afterwards.

The traumatic form of the disease has occasionally occurred, chiefly as a result of vene-section, at one time so much in vogue among the common people, especially on the conti-nent of Europe. Examples of the accident have been recorded by Guattani, Roux, Vidal, and other writers. From the firm support which the artery receives as it passes over the tarsal bones in front of the foot, the probability is that such a tumor might easily be obliterated by compression, either digital or mechanical, applied immediately below the ankle-joint. If the effort should fail, the tumor should be dissected out, and the artery tied above and below.

SECT. VIII.—OPERATIONS ON THE ARTERIES.

LIGATION OF THE INNOMINATE OR BRACHIO-CEPHALIC.

Although the innominate may be easily exposed on the dead subject, as was shown by Dr. George McClellan as early as 1820, by a linear incision carried vertically down in front of the trachea, without dividing any of the cervical muscles, yet I believe that such a plan would be ill suited to the purpose when there is a large tumor pressing upon and displacing the parts which environ this vessel. The operator must have ample room, and it will not, I presume, materially affect the issue of the case whether a little more or a little less tissue is cut. The plan suggested by Dr. Mott, in his celebrated case, is, on the whole, it seems to me, the one best adapted for obtaining ready access to this artery, and is that which I should myself follow if I were called upon to secure the innominate for the cure of aneurism. The incision resembles, in outline, the shape of the letter L, the horizontal limb corresponding with the upper border of the clavicle and sternum, and the vertical with the inner margin of the sterno-cleido-mastoid muscle, each being about three inches in length. The lower incision extends as far inwards as the centre of the trachea. The triangular flap thus mapped off, embracing the skin and platysma-myoid, being dissected up, the sterno-cleido-mastoid, sterno-hyoid, and sterno-thyroid muscles are respectively separated upon a director from their inferior connections and turned out of the way. A layer of the deep cervical fascia is now cautiously pinched up and divided, when, by a little scratching with the finger-nail, the handle of the scalpel, or the end of a probe, the carotid will be brought into view a few lines above the top of the sternum, accompanied by the jugular vein and pneumogastric nerve. Taking this vessel as his guide, the surgeon can easily trace the course of the innominate downwards towards the heart, and isolate it from its associate vein. The ligature, when the case admits of it, should be applied about the middle of the vessel, the needle being carried around it from left to right and from behind forwards. When the aorta is situated unusually low, it may be necessary, in order to obtain more easy access to the innominate, to excise, as a pre-liminary step, the external extremity of the clavicle with a small segment of the sternum, as was done by Cooper, of San Francisco, in both his cases.

In performing this operation, it should be remembered that this artery is only about sixteen lines in length ; that it rests upon the trachea, which it crosses somewhat obliquely at the base of the neck ; that the middle thyroid veins, and sometimes the middle thy-roid artery, run along its inner side ; and that on the right side, and on a plane ante-rior to it, is the innominate vein, the two vessels being intimately united together by connective tissue, and in close relation behind with the pneumogastric and phrenic nerves, the latter lying external to the former. The top of the pleura is a little inferior and external to the artery, and might, unless great caution is used, be easily wounded. The middle thyroid artery is sometimes given off by the innominate on its tracheal as-pect, and should be looked for in isolating the vessel, as its division might be followed by annoying hemorrhage.

LIGATION OF THE COMMON CAROTID.

To Mr. Abernethy is usually, but erroneously, ascribed the merit of having first tied the common carotid. From some remarks of Hebenstreit, it appears pretty certain that the operation had been performed some time previously by a surgeon during the extirpa-tion of a tumor of the neck, in which he accidentally divided this vessel, and immediately surrounded it with a ligature, the patient soon recovering. The English surgeon did not

ligate the artery until 1798 ; the case was one of wound of the internal corotid, and the man died in thirty hours. The first operation that was performed upon it for carotid aneurism was by Sir Astley Cooper, in 1805, and was unsuccessful, the case terminating fatally on the nineteenth day. Three years subsequently, he ligated the vessel again, and now with a happy result.

There are two points at which the common carotid may be tied, the place of election being regulated by the circumstances of the particular case. These are the upper and inferior cervical regions, and it will be well, in every instance, before the operation is begun, to call to mind the more important anatomical relations of the parts, otherwise serious blunders may arise, such, for example, as tying the omo-hyoid muscle or jugular vein instead of the artery, or including along with the artery the vessel just named, or some important nerve, as the pneumogastric, sympathetic, or laryngeal. As the artery proceeds upwards, it is overlapped by the sterno-mastoid, sterno-hyoid, and sterno-thyroid muscles, and crossed by the omo-hyoid towards its superior extremity. Running down in front of its sheath is the descending branch of the ninth pair of nerves, a little, thread-like filament, easily recognized by its whitish appearance, while within the sheath are, on the external side of the artery, the internal jugular vein, and behind and between them the pneumogastric nerve, the sympathetic and recurrent being posterior to the sheath. These relations are very intimate, and, therefore, the utmost caution is necessary in isolating the parts previously to the application of the ligature. The embarrassment is often immensely increased by the manner in which the artery is overlapped by the jugular vein, which occasionally, although less frequently than is generally supposed, swells out enormously during every effort at expiration, so as to obscure the vessel and render its ligation extremely difficult. The best way of remedying this is to request an assistant to compress the vein both at the upper and lower angle of the wound, the blood having previously been pressed out of it.

The common carotid, on the right side, is sometimes absent, its place being supplied by two trunks, which, arising separately from the arch of the aorta, ascend along the neck, assuming the office of the external and internal carotid. When this arrangement exists, which, however, is extremely rare, the order of origin of the branches of the aorta is as follows : the right subclavian, right external carotid, right internal carotid, left common carotid, and left subclavian. It should also be borne in mind that the common carotid may, on the other hand, bifurcate very low down, not perhaps reaching as high up as the inferior border of the thyroid cartilage, and, on the other hand, it may not separate into its terminal divisions until it gets to the angle of the jaw. Morgagni met with an instance in which the artery, only an inch and a half in length, divided at the root of the neck. Lastly, it may be crossed in front by the inferior thyroid artery, lie upon the vertebral artery as this vessel passes along the spine, and include in its sheath the descending branch of the ninth pair of nerves.

In ligating the carotid, the patient should be recumbent, with the head inclined to the opposite side, and well supported by pillows, the shoulders being at the same time somewhat raised, in order to place the neck in a proper horizontal position. In the lower part of the neck the artery may be exposed by making an incision, from two and a half to three inches in length, along the inner border of the sterno-cleido-mastoid muscle, commencing just above the clavicle. The skin and platysma-myoid muscle being divided, a portion of the cervical fascia is pinched up with the forceps, and opened transversely to an extent large enough to admit a grooved director, upon which the membrane is then slit up and down nearly to the length of the outer incision. Two retractors are now inserted into the wound, one being used to draw the sterno-cleido-mastoid muscle outward, and the other to draw the sterno-thyroid inwards toward the trachea. The sheath of the artery being thus exposed, a little piece of it is now raised with the forceps, and divided horizontally, when, the director being introduced, it is slit open so as to denude the artery to a small extent, and enable the operator to isolate it from the jugular vein and the pneumogastric nerve, the ligature being passed from without inwards. Generally a small subcutaneous vein will be found passing along the line of incision, communicating above with the facial vein, and below with the thyroid plexus. This must, of course, be carefully avoided.

The artery being more easy of access in the superior part of the neck than the inferior, this point should always be selected, when this is in our power, for ligating it. To expose the vessel in this situation, an incision should be carried along the inner margin of the sterno-cleido-mastoid muscle, commencing a little below the cricoid cartilage, and reaching nearly as high up as the angle of the jaw. Embracing the integument, platysma-

myoid muscle, and cervical fascia, it will thus conduct the operator at once down to the sheath of the vessel, which is then to be opened in the same cautious manner as in the previous case ; and the artery being gently separated from the accompanying structures, is ligated by passing the needle around it from without inwards, so as effectually to exclude the jugular vein. The omo-hyoid muscle, which crosses this part of the carotid, must be held aside with a hook.

The annexed cut, fig. 345, from Bryant, represents the common carotid as being exposed by a long incision, with a view of showing where it is crossed by the omo-hyoid muscle.

Fig. 345.
Ligation of the Common Carotid and Facial Arteries.

When access to the common carotid, in the inferior part of the neck, is rendered difficult on account of the low situation of the tumor, the best plan is to divide the sterno-hyoid and sterno-thyroid muscles, either alone, or jointly with the inner portion of the sterno mastoid, so as to enlarge the space between the aneurism and the sternum. By observing this precaution, Mr. Porter, of Dublin, was enabled, in one case, to ligate the vessel successfully within the eighth of an inch of the innominate ; and examples of a similar character have occurred in the practice of other surgeons.

The carotid is sometimes tied at a very early age, as in a case in which I assisted the late Dr. George McClellan, where he successfully secured this vessel in a child five months old, on account of an immense nævus of the upper part of the face. The descending branch of the ninth pair of nerves was divided, as it interfered with the passage of the ligature, without any apparent harm. Dr. Valentine Mott, in a similar affection, tied the common carotid in a child only three months old, the whole of the operation being equally gratifying.

Ligation of the common carotid is occasionally required on account of wounds of the neck involving the external carotid or some of its branches. The first successful case of the kind occurred in 1803, in the hands of Mr. Fleming, an English naval surgeon. The operation is often embarrassing in consequence of the confused condition of the parts from the extravasation of blood, and is, besides, not always successful, owing to the establishment of a return current through the internal carotid into the external carotid. Hence secondary hemorrhage, sometimes of a very profuse character, is liable to ensue, necessitating further proceeding, at a time, perhaps, when the wound is in a high state of inflammation. In order to avoid all this, Dr. Gurdon Buck has proposed the simultaneous ligation of the common and internal carotid arteries, and, in the New York Medical

Times for November, 1855, he has given the particulars of a case in which the operation was followed by the most gratifying results.

Ulcers of the fauces have sometimes necessitated the ligation of the primitive carotid, as in the cases reported by Luke, Mayo, and Syme, in all of which the operation was successful. The patient of the latter, however, came very near perishing from secondary hemorrhage.

The common carotid artery has been repeatedly secured for wounds, ulcers, epilepsy, and erectile and other tumors, as well as for restraining hemorrhage in operations and injuries upon and about the head, ear, jaws, face, neck, mouth, and pharynx. The statistics of these operations present points of much interest, and they have been placed in a very clear light by the tables of Dr. Norris. In 30 cases in which the artery was tied on account of wounds, 15 recovered, and 15 died; in 16 cases in which it was ligated previously to, or at the time of the extirpation of, tumors of the jaw, face, or neck, 8 died; in 6 in which it was tied for the cure of epilepsy, all recovered, from the effects of the deligation, although in 2 both vessels were secured; and in 42 cases in which it was tied for the cure of erectile tumors and various growths of the diploë, orbit, neck, jaw, and maxillary sinus, 20 were cured, 13 died, and 9 recovered from the effects of the operation without being materially benefited. In upwards of 20 of the 94 cases, more or less severe cerebral symptoms followed the operation.

Of 600 cases of ligature of the common carotid artery, analyzed by Dr. C. Pilz, of Breslau, in 1868, 319 were cured, 259 died, and of the remainder the result is not stated. Of 537 cases in which the sex is given, 403 were males and 134 were females. In 578 cases, in which the result is recorded, the ligature was applied in 222 for hemorrhage, in 86 for aneurism, in 136 for tumors, in 63 before and during the removal of tumors, in 34 for nervous affections, and in 37 for Brasdor's operation. In 27 cases both arteries were tied, the right in 251, and the left in 194. In the majority of instances, the ligature was detached after the thirtieth day. Nervous affections followed the operations in 160 cases, and hemiplegia in 8 per cent.

These figures are not materially affected by those of Dr. Wyeth published in 1879. Thus, for instance, of 462 cases of wounds of all kinds for which the common carotid was tied 262 proved fatal. Of these cases 111 were gunshot wounds contracted in military service with a mortality of 81, while of 16 cases in civil life, only 4 died, thus presenting a difference in favor of the latter of 48 per cent., due mainly to the milder form of the injury, and to the less amount of shock. The table of Dr. Wyeth includes 52 cases of ligation for non-malignant tumors of the orbit, of which 28 were cured, 6 died, 5 were improved, and 6 were not benefited. Of 71 operations performed for the relief of aneurism by anastomosis, not affecting the orbit, 51 recovered, with 20 cures, and 20 died. Of 166 cases in which the artery was tied for sacculated aneurism 76 died, and of the 90 recoveries only 66 were cured. Of the 166 cases the artery was tied on the cardiac side of the tumor in 106, of which 37 perished, and 90 recovered with 60 cures. Of 60 cases in which the ligature was applied at the distal side of the aneurism 39 died, and 21 recovered, but only 6 were permanently relieved.

Wyeth's tables comprise 789 cases of ligation of this artery for all causes, of which 323, or 41 per cent., perished. Of the 466 cases reported as having recovered, only 255 were cured, 42 were improved, 14 temporarily benefited, and 53 unimproved. The principal factors of death in the fatal cases were, hemorrhage, exhaustion, and cerebral disturbance, or interference with the functions of the brain, from the want of blood, and other causes. Paralysis followed the ligation of the artery in 52 of the 789 cases. Of the 323 fatal cases 7½ per cent. occurred within the first 24 hours after the operation; 23 per cent. within three days; 45 per cent. within one week; 64 per cent. within a fortnight; and 75 per cent. within twenty-one days. The same artery was tied twice in 8 instances with six fatal results, and in one thrice followed by death. The right artery was ligated in 361 cases, and the left in 290 of the 651 in which the seat of the operation is stated. The ligature was detached on an average, from the tenth to the twenty-fourth day. Among the great dangers after the operation are softening of the brain and inflammation of the air-passages. A very distressing symptom occasionally witnessed is violent hiccough, due, apparently, to compression of the pneumogastric nerve by the ligature.

In wounds of the neck, involving the great vessels, the common carotid should never, as has been justly remarked by Dr. Wyeth, be tied for injury of the external carotid, or of its branches, when there is space enough between the seat of the lesion and the bifurcation of the common carotid to admit of the application of a ligature to the external carotid. He bases this conclusion upon the fact that the death-rate in 789 cases tabulated

by him of ligation of the common carotid is 41 per cent., while that of the external carotid in 91 cases is only 4½ per cent. He also lays great stress upon an analysis of 121 dissections made by him with a view of determining the relations of these arteries and of their branches to each other. He condemns, in pointed language, the teaching which advises the ligation of the common trunk instead of the external carotid when there is sufficient space between them to place the ligature; he declares that the practice, hitherto almost universal, is as wrong in principle as it is dangerous in its results, and should therefore be abandoned.

The following table affords a summary view of nearly all the examples in which both these vessels have been tied, either simultaneously or after a variable interval.

Ligation of both Carotids.

No.	Operator.	Date	Age	Sex	Diseases.	Interval.	Result.	Remarks.
1	Dupuytren and Robert	1819	...	...	Anastomotic aneurism of scalp.	36 years	Died	Brain symptoms.
2	Macgill	1823	...	F.	Fungous tumor of both orbits.	1 month	Recovered	Improved. Vision destroyed before operation.
3	Ullman	1823	20	...	Erectile tumor of orbit.	12 months	Died	Death on 3d day from hemorrhage.
4	Mussey	1827	20	M.	Anastomotic aneurism of scalp.	13 days	Recovered	Failed. Pulsation returned in tumor, which was excised after second operation.
5	Mussey	1827	19	...	Anastomotic aneurism of scalp.	28 days	Recovered	
6	Möller	1831	4½	...	Erectile tumor.	4½ months	Recovered	
7	Preston	1831	24	M.	Epilepsy.	39 days	Recovered	Failed. Convulsions the day after each operation.
8	Preston	1831	51	M.	Epilepsy.	84 days	Recovered	Failed. Fits had existed for six years, latterly palsy on one side.
9	V. Mott	1832	...	M.	Epilepsy.	6 months	Recovered	
10	V. Mott	1833	...	M.	Disease of parotid.	15 min.	Died	Death in forty-eight hours.
11	Kuhl	1834	53	M.	Aneurism of occiput.	72 days	Recovered	
12	Hamilton	1838	18	M.	Epilepsy.	6 months	Recovered	Last operation followed by destructive inflammation of the left eye.
13	Velpeau	1839	29	...	Aneurism of both orbits.	3 months	Recovered	
14	V. Mott and Eve	1839	19	M.	Hemorrhage from nasal polyp.	13 months	Recovered	
15	Pirogoff	1843	20	...	Hemorrhage from aneurism of scalp.	1 year	Recovered	Hemorrhage and vomiting after each operation.
16	J. Ellis	1844	21	M.	Shot wound of tongue.	4½ days	Recovered	
17	Reynolds & Van Buren	1844	11	...	Aneurism by anastomosis.	6 years	Recovered	
18	J. M. Warren	1845	23	M.	Erectile tumor of face.	33 days	Recovered	Failed. Subsequent excision of diseased structure followed by cure.
19	Robert	1846	19	F.	Aneurism of forehead	8 months	Recovered	Headache; temporary disturbance of vision.
20	Blackman	1848	15	M.	Disease of antrum.	21 days	Recovered	Temporary loss of vision of left eye.
21	V. Mott	1851	...	M.	Malignant disease of nose.	5 months	Recovered	
22	W. Parker	1854	45	M.	Malignant disease of nose and orbit.	32 days	Recovered	Died at end of five months from return of the disease.

No.	Operator.	Date.	Age	Sex	Diseases.	Interval.	Result.	Remarks.
23	V. Mott	1854	...	M.	Malignant disease of orbit.	3 months	Died	Death on fourth day.
24	J. R. Wood	1856	53	...	Encephaloid of antrum.	5 months	Died	Death on sixteenth day.
25	Buck	1857	22	M.	Aneurism of orbit.	26 months	Recovered	
26	G. C. E. Weber	1857	20	M.	Epilepsy.	17 days	Recovered	Improved. Disease had existed for five years.
27	Carnochan	1858	44	F.	Elephantiasis of neck, ear, and face	7 months	Recovered	Growth, which had existed for fourteen years, diminished.
28	V. Mott	1858	21	M.	Malignant disease of antrum.	8 months	Recovered	
29	U. S. Army ?	1862	...	M.	Shot wound of neck.	Same day	Died	Death same day.
30	Murdoch	1863	...	M.	Shot wound of neck.	3 days	Died	Death on fifth day after second operation from recurrence of hemorrhage.
31	Longmore	1863	...	...	Shot wound	6 days	Died	Death in thirty-eight hours.
32	Billroth	1864	27	...	Hemorrhage from ulcerated internal carotid artery.	14 days	Died	Secondary hemorrhage on sixteenth day. Death two days after second operation from exhastion.
33	Lewis	1864	...	M.	Shot wound of face.	4 days	Died	Death on ninth day.
34	Parker	1864	38	M.	Malignant disease of antrum.	28 days	Recovered	Disease not arrested.
35	H. E. Foote	1867	20	M.	Orbital aneurism.	30 days	Recovered	Complete cure of aneurism, and marked improvement of vision.
36	Buenger	......	34	...	Aneurism by anastomosis and wound.	5 years	Recovered	Left tied for aneurism, and the right for suicidal wound five years afterwards.

Of the above cases, 36 in number, 26 recovered from the effects of the operation, and 10 died. In the instance of Dr. Mott, in which both vessels were tied almost simultaneously, coma soon supervened, and the man died in forty-eight hours. In the case of Dr. Ellis, of Michigan, the second deligation was performed after an interval of four days and a half, on account of secondary hemorrhage consequent upon a gunshot wound, and no unpleasant symptoms followed, the patient making an excellent recovery. In Dr. Mussey's case twelve days intervened between the two operations, neither of which was succeeded by any accident. To Dr. Macgill, of Maryland, belongs the credit of being the first to tie both carotid arteries on the same subject within a short interval.

Most of the cases marked as recoveries were only temporarily relieved; very few were cured. Most of the cases in which the operations were performed for gunshot injuries perished from secondary hemorrhage. Of 22 operations performed by American surgeons 17 recovered, and 5 died.

LIGATION OF THE EXTERNAL CAROTID AND ITS BRANCHES.

The external carotid, extending from the superior border of the thyroid cartilage to the neck of the lower jaw, is situated, just above its origin, in the triangular space formed by the omo-hyoid muscle below, the digastric above, and the sterno-mastoid externally, immediately beneath the integument and platysma-myoid; but it soon sinks deeper in, passing up under cover of the stylo-hyoid and digastric muscles, and is finally buried in the substance of the parotid gland. It is accompanied by two veins, and is crossed near its commencement by the hypoglossal nerve, and also, in various parts of its course, by branches of the external jugular and other veins. The glosso-pharyngeal nerve is interposed between this artery and the internal carotid, while the superior laryngeal nerve lies under both.

Ligation of the external carotid artery is seldom required except in wounds of the neck

and in vascular growths, as nevoid tumors and aneurism by anastomosis, of the face and scalp. The operation has occasionally been performed as a preliminary step to the removal of the lower jaw and of the parotid gland, but such a measure can certainly rarely be necessary in the hands of a skilful surgeon; and, as for tying this vessel for the cure of carcinoma of the neck, tongue, palate, or pharynx, as has been done by Mutzer, Maisonneuve, and others, I hold that such a procedure, in the face of our present experience, is utterly unjustifiable. The vessel is often opened in attempts at suicide, although less frequently than is generally imagined; for persons intent upon self-destruction usually bend the neck so far back as to place the artery beyond the reach of the knife. Some of its branches are, however, commonly injured under such circumstances, especially the superior thyroid and lingual, and the hemorrhage thus produced may be promptly fatal. A ligature may readily be placed around the external carotid between these two arteries, in the first part of its course, that is, from four to six lines above its origin, and immediately below the digastric muscle, by carrying an incision, about two inches and a half in length, parallel to and about six lines in front of the inner edge of the sterno-mastoid muscle, commencing opposite the middle of the thyroid cartilage, and terminating a short distance below the angle of the jaw. The trunk of the common carotid will guide the finger to its external division; and it will always be well, before the ligature is tied, to feel for the pulsation of the temporal artery. The incision should be made with great care, lest violence be done to some of the numerous offsets of the vessels. The artery, as it lies beneath the digastric and stylo-hyoid, is exposed with difficulty; the incision must be proportionately large, and the muscles just mentioned must be well depressed with the retractor.

Some of the branches of this artery occasionally arise so closely to its origin as to render it improbable that if a ligature were applied at the usual point of election, a sufficiently large and firm clot would form to occlude its caliber securely on the detachment of the ligature. For such a case the safest plan would be to tie at the same time the nearest offset.

Dr. Wyeth, in his statistics, finds that the external carotid artery was tied alone in 67 cases with 3 deaths, and simultaneously with the common carotid in 10 cases, all of which

Fig. 346.
Ligation of the Subclavian and Lingual Arteries.

ended fatally. Of the 64 recoveries, in which the external carotid alone was concerned, only 31 are reported as having been cured. Of the 67 cases, the sex is given only in 47, of which 34 were males, and 13 females. The ligature, in most of the cases, came away before the seventeenth day, in one as early as the fifth day, and in one as late as the twenty-second

day. The artery was tied on both sides in the same patient in six cases, all eventuating in recovery. The causes necessitating the operations were various, as wounds, hemorrhages, tumors, malignant and benign, and vascular growths of the head, ear, face and nose, facial neuralgia, and injury of the external carotid and facial arteries.

The principal branches of this artery, requiring surgical consideration, are the superior thyroid, lingual, facial, occipital, and temporal.

The *superior thyroid artery* is much exposed to injury in attempts at suicide, and may then be easily traced simply by following the wound. If it becomes necessary to ligate it on account of hypertrophy of the thyroid gland, with a view to diminish the supply of blood, it may be laid bare by making an incision across the upper part of the neck, obliquely downwards and outwards from the side of the hyoid bone to the edge of the sternomastoid muscle. Or, instead of this, the object may be attained by making an incision, two inches in length, along the inner border of the sterno-mastoid muscle, as in the operation for tying the external carotid. The skin, platysma-myoid, and cervical aponeurosis having been carefully divided, the superior thyroid will be found deep in the omohyoid space, between the sheath of the carotid and the thyroid gland.

The *lingual artery* may be exposed in the same manner as the thyroid, near which it takes its origin; its situation, however, is very deep, and its relations are so complicated that it generally requires a great deal of skill and perseverance to reach it. Unless the patient is fully under the influence of an anæsthetic, the difficulty of the operation will be much increased by the incessant spasmodic action of the larynx, which, forcing the hyoid bone up and down, renders it very troublesome to fix the points of incision.

If the operation, fig. 346, from Bryant, should be deemed necessary, it may be performed as follows, according to the plan laid down by Mr. Skey in his valuable work on Operative Surgery : " The head of the patient being placed horizontally, and the neck lengthened by raising the chin, an incision of about twelve lines in length should be made immediately behind the cornu of this bone, the outline of which should be distinctly ascertained before proceeding to the operation; the incision should be directed downwards and forwards. The skin and platysma being divided, the fascia is exposed, which should also be divided to the length of the external wound. The facial vein, often of considerable size, will be brought into view at the upper part of the wound, in its course downwards to the internal jugular, and should be drawn outwards. The remaining parts should be torn, rather than cut asunder, passing transversely inwards, nearly parallel to the upper edge of the cornu of the os-hyoides, when the artery will be exposed. In passing the needle behind it, care must be taken to avoid the superior laryngeal nerve, which descends nearly at right angles behind the artery."

Demarquay has tied both lingual arteries on three occasions, to produce atrophy of carcinomatous affections of the tongue, with the result of prolonging life in each case; and a similar operation for gunshot wound of the tongue was successfully performed during the War of the Rebellion.

The *facial artery*, so frequently concerned in operations about the neck, face, and lips, may easily be compressed with the finger as it passes over the jaw. If divided, it should immediately be secured. When its ligation becomes necessary, in case there is no wound, its pulsation will point out the proper situation for the incision. When it is desired to secure it just above its origin, the incision should be made as in the operation upon the lingual, its approach being facilitated by drawing the digastric muscle strongly upwards. The vessel is most easily exposed and tied where it lies over the jaw, as in fig. 345.

The *occipital artery* sometimes requires ligation on account of wounds, but its depth in the lower part of its extent is such as to protect it generally from injury involving the cervical region. On the back of the head, however, it is not unfrequently laid open, and usually bleeds very freely. It may be exposed just above its origin by carrying an incision along the inner border of the sterno-mastoid muscle, in the angle formed by it and the digastric, the latter of which must be well drawn down. It is in intimate relation here with the hypoglossal nerve, which hooks around it as it passes forward toward its destination. The artery, after emerging from the splenius muscle, on the back of the head, fig. 347, is superficial, its course beneath the scalp being denoted by its pulsation. A fatal case, in which, on account of a wound in this vessel, and of the jugular vein, and the confused condition of the parts, a ligature was applied to the common carotid artery by Dr. G. W. Norris, is reported in the American Journal of the Medical Sciences for April, 1856.

The *temporal artery* is occasionally wounded, and may be secured immediately above the zygoma, by a short vertical incision, fig. 348, embracing the temporal aponeurosis,

immediately beneath which it is situated.   Lower down, the depth at which it lies is too great to justify an attempt at ligation.   Should it be divided in this portion of its extent, the best plan is to tie the external carotid.

Fig. 347.

Ligation of the Occipital Artery.

Fig. 348.

Ligation of the Temporal Artery.

The anterior branch of this vessel is the one always selected in arteriotomy, when it is wished to practice depletion on account of affections of the brain, or the brain and its membranes.   After a sufficient amount of blood has escaped, the artery is cut across, and a graduated compress applied.   If this precaution be neglected, a false aneurism will form.

The *internal maxillary artery* is sometimes wounded by a thrust with a sharp knife or dirk.   The immediate result, of course, is a copious hemorrhage, for the arrest of which the only remedy is ligation of the external carotid: compression, it is true, now and then succeeds, but the only reliable means is the ligature.   When the vessel is wounded in the extirpation of the jaw, it may commonly be seized and tied; when this is impracticable, the bleeding may generally be stopped with the hot iron, or with the tampon, wet with a saturated solution of subsulphate of iron.

LIGATION OF THE INTERNAL CAROTID ARTERY.

Ligation of this vessel is rendered necessary for the arrest of hemorrhage, and for the cure of traumatic aneurism, the result of injury inflicted upon its own tunics.   Varying in length in different individuals, the artery extends directly upwards from the upper border of the thyroid cartilage to the carotid foramen of the temporal bone, and is in intimate relation with numerous and most important structures.   Lying deeply in the neck upon the anterior rectus muscle, it is concealed below by the sterno-mastoid muscle, and above by the parotid gland, the internal jugular vein being situated at its posterior aspect, and somewhat superficial to it, the pharynx and tonsil at its inner side, and the pneumogastric and sympathetic nerves deeply behind.   The main trunk of the external carotid is on the outside, and a little in front of it.   Superiorly, the artery is crossed by the digastric and stylo-hyoid muscles, the occipital artery, and the glosso-pharyngeal nerve, and, near the base of the skull, by the styloid process, and the stylo-pharyngeal muscle.

Considering the intricate relations of this vessel, the narrow space in which it is embedded, and the fact that in cases of injury the parts must necessarily be greatly confused by extravasated blood and inflammatory deposits, some idea may be formed of the great difficulty which the surgeon must experience in any attempt to cast a ligature around it.   In order to expose the artery, the anterior border of the sterno-mastoid muscle must be taken as a guide to the knife, and an incision made from three to five inches in length, an abundance of room being indispensably necessary to success.   Two ligatures are required—one above and the other below the seat of injury—when the vessel is secured on account of hemorrhage, or for the cure of traumatic aneurism.   This fact, long ago pointed out by Guthrie, was strikingly illustrated in the case of Professor Briggs, of Nashville, in which the artery was tied in 1871, for aneurism, and in that of Professor H. B. Sands, of New York, in which it was ligated in 1872, on account of secondary hemorrhage, consequent upon the extirpation of the lower jaw.   In both of these examples, as well as in every other, so far as I have been able to ascertain, in which the common carotid artery was secured for the suppression of hemorrhage of the internal carotid, the

patients perished from loss of blood. When the artery is ligated on account of hemorrhage from the ear, the tonsil, or epithelioma of the throat, as in the cases reported, respectively, by Billroth, A. Smith, and Von Langenbeck, only one ligature will be required.

The case of Professor Briggs was one of traumatic aneurism in a man twenty-three years of age, the result of a stab received six weeks before. The tumor, which was as large as an ordinary fist, and occupied the left parotid region, was laid very freely open, the clots turned out, and the artery tied above and below the wound, the common carotid having been previously secured without any effect upon the hemorrhage. In Professor Sands's case, the internal carotid artery gave way ten days after disarticulation of the left half of the lower jaw, performed on account of malignant disease in a man fifty-three years of age. Two ligatures were applied, one on the proximal and the other on the distal side of the ulcer in the vessel, and immediately after a ligature, previously placed around the common carotid artery, was tightened. All bleeding now ceased. The two ligatures around the internal carotid separated on the ninth day, and that on the common carotid on the fourteenth day, followed by complete recovery.

The ligation of this vessel may be greatly facilitated, especially as has been suggested by Guthrie, when it has been wounded through the mouth, by severing the lower jaw at the second molar tooth. By drawing the posterior fragment outward, increased space will be obtained which will be of material assistance in the efforts necessary to pass and tie the ligature. In performing any operation upon this vessel, the surgeon must be in full possession of a knowledge of the anatomy of this part of the neck, otherwise his efforts will be sure to eventuate in disappointment, if not in discomfiture and disgrace.

The statistics of this operation are very unsatisfactory. Wyeth has found only 19 cases, and in only two of these was the internal carotid alone tied. In 6 cases, the common carotid was tied at the same time, with 3 cures and 3 deaths; in 3 the external, all being successful; and in 6 cases the common, external and internal, 3 recovering and 3 dying. In one instance, the internal carotid and internal jugular vein were tied, the result being favorable, and in another case, equally successful, the three carotids and internal jugular vein were ligated. The operation in 14 cases was performed for hemorrhage, of which 5 died; in one, for aneurism, followed by recovery, and in a fatal one for an erectile tumor. The 2 cases in which the internal carotid alone was ligated recovered.

LIGATION OF THE SUBCLAVIAN AND ITS BRANCHES.

The point which is usually selected for tying the subclavian artery is just external to the scalene muscle, in what is considered as the third course of the vessel, excellent illustrations of which are afforded by fig. 346, from Bryant, and fig. 349, from Erichsen. One single incision will generally be found to be sufficient for the free exposure of the artery, and this may be strictly horizontal or more or less curvilinear, according to the fancy of the operator. It is only when the tumor is so bulky as to cause great malposition of the shoulder, forcing the collar-bone high up into the neck, that two incisions can really be required, the one extending along the upper border of the clavicle, and the other vertically upwards, parallel with the outer edge of the sterno-cleido-mastoid muscle.

Fig. 349.

Diagram of Right Subclavian Artery in Third Part of its Course, crossed by transverse cervical artery and vein. *a*. Subclavian artery. *v*. External jugular receiving the transverse cervical veins. *n*. Brachial plexus of nerves. *m*. Omohyoid muscle.

The patient, in this operation, rests in the horizontal position upon a narrow table, with his head and chest moderately elevated, and the face slightly inclined towards the sound side. An assistant taking hold of the hand keeps the affected limb close to the trunk, at the same time that he pulls down the shoulder as much as possible, in order to draw the clavicle away from the subclavian artery as it passes from the scalene muscle towards the first rib. The surgeon, standing by the side of the patient, above the shoulder, stretches the integument of the neck upon the upper part of the chest with the fingers of the left hand, while with the other he makes an incision, about two inches and a half in length, directly along the middle of the clavicle, commencing at the sternal origin of the mastoid muscle and terminating near the anterior margin of the trapezius. In this manner he divides the skin, superficial fascia, and platysma-myoid. Letting go his hold with his left hand, the parts will be found instantly to resume their natural

situation, leaving thus the incision on a level with the superior border of the clavicle. The next step of the operation consists in detaching from this bone the deep cervical aponeurosis, which may readily be accomplished by a few gentle strokes of the handle of the scalpel instead of the point of the instrument, which would greatly endanger the surrounding vessels and nerves. The external jugular vein will be found close to the outer edge of the mastoid muscle, and should be held out of the way with a blunt hook. The suprascapular artery will also generally appear, at this stage of the procedure, just above and behind the clavicle, or partially covered by it, and should be treated in a similar manner; or, if divided, it should immediately be tied. The omo-hyoid lies at the outside of the incision, bound down by a process of the cervical aponeurosis, which should next be torn through with the knife. Taking the anterior scalene muscle for his guide, the operator feels for the tubercle of the first rib, a little to the outside of which the artery will be found pulsating, more or less distinctly, and where it may generally be easily secured by passing the needle from before backwards and from below upwards. Previously to tightening the ligature, it should be ascertained that it controls the circulation in the aneurismal sac, and, above all, that it does not include any of the cords of the axillary plexus of nerves, a circumstance which has happened in several of the cases in which this operation has been performed. When the clavicular origin of the sterno-mastoid muscle is unusually broad, as it not unfrequently is, it should be divided upon the grooved director, as this will greatly facilitate the approach to the vessel, particularly when the design is to apply the ligature behind the scalene muscle.

In this manner, the subclavian may generally be easily reached without much loss of blood or waste of time. In some instances, however, the operation is rendered extremely difficult, tedious, and embarrassing, owing either to the magnitude of the tumor and the consequent elevation of the clavicle, the diseased state of the artery, the unusual course of the vessels of the neck, or even when these follow their natural direction, the swollen and distended condition of the subclavian vein, the irregularity of the omo-hyoid muscle, the enlarged condition of the cervical lymphatic glands, the great condensation of the parts from the effusion of plastic matter, or, finally, the upward extension of the pleura.

1. The *elevation of the clavicle* is generally in direct proportion to the size of the tumor. Sometimes, however, even when the swelling is comparatively diminutive, this bone is situated much higher up than usual, owing to the peculiar conformation of the individual. In either case, the difficulty of finding the vessel will be much increased. In one instance, in which the elevation was produced by the enormous development of the disease, Sir Astley Cooper was forced to abandon the operation altogether. When such a contingency arises, which, on the whole, must be extremely rare, instead of giving up the case in despair, as was done by the English surgeon, the best plan, it seems to me, would be to divide the anterior scalene muscle, so as to enable us to apply the ligature somewhat nearer to the heart, or even on the tracheal side of that muscle.

2. The operation is occasionally rendered more or less intricate and embarrassing by the *diseased state of the artery*. In this case, although the vessel may be easily enough approached, it is impossible to apply the ligature at the usual situation. To divide the scalene muscle, or to cut down along its margin, for the purpose of securing the vessel at one or other of these points, is here our only resource. The brachial plexus of nerves may also be so much in the way of the operator as to render this course necessary, as happened on one occasion to Dupuytren.

3. The *cervical vessels*, both arterial and venous, are almost constantly in the way of the operator, even when they pursue their usual route. This is particularly true of the external jugular vein and of the suprascapular artery. The former of these vessels, commencing at the angle of the jaw, passes vertically down the neck under cover of the platysma-myoid. In the early stage of its course, it rests upon the sterno-mastoid; afterwards it gets to the outer border of this muscle, and, finally, at the inferior part of the neck, sinks behind it, to terminate in the subclavian vein near its junction with the internal jugular. Just before it disembogues, which it sometimes does by several distinct trunks, it receives two pretty large branches, the suprascapular and transverse cervical, which traverse the neck in a horizontal direction from without inwards, parallel with the arteries of that name. These arteries, as well as their accompanying veins, lie deeply at the root of the neck, especially the suprascapular, which is frequently concealed for some distance by the clavicle, on a line with which it runs to reach the root of the coracoid process; it is generally a branch of the thyroid axis, and rests at first upon the anterior scalene muscle, crossing as it passes outwards the subclavian artery. The course of the transverse cervical artery is nearly similar, but it is usually situated somewhat higher up;

it is also considerably smaller, and is not unfrequently derived immediately from the subclavian.

Now, in attempting to reach the subclavian, it is almost impossible to avoid wounding some of the vessels above mentioned. The external jugular vein is particularly in danger, and can scarcely escape without the utmost coolness and dexterity on the part of the operator. As soon as it is recognized, it should be separated from the surrounding structures by a few gentle strokes with the handle of the scalpel, and drawn to the outer side of the wound. This plan is undoubtedly always the best and safest when it can be adopted; sometimes, however, it happens that the vessel is so much in our way as not only greatly to embarrass our progress, but absolutely put a stop to it. In this case it must be tied with two fine ligatures, and then divided. Such a procedure not only prevents hemorrhage, but also the introduction of air into the lower portion of the vessel, an occurrence which cannot be too carefully guarded against. The suprascapular artery, if in the way, should be drawn aside, or, if it be wounded, immediately secured. Any bleeding vessels, indeed, no matter whether arterial or venous, provided they pour out a sufficient amount of blood to interfere with the operation, should at once be tied.

4. The inordinate *swelling of the subclavian vein* is another source of embarrassment occasionally experienced in operations of this kind. This vessel is usually situated somewhat below and superficially to the artery, being separated from it by the anterior scalene muscle, upon which it lies. Commencing at the inferior margin of the first rib, where it is continuous with the axillary, it passes horizontally inwards until it joins the internal jugular vein, within a few lines of the sterno-clavicular articulation. In this course, in which it is almost entirely concealed by the clavicle, it receives the small branches which accompany the different offsets of the artery as well as the external jugular, which last enters it, as before stated, nearly opposite the centre of the bone, but sometimes more internally. After the division of the cervical aponeurosis in the lower part of the neck, the operator will occasionally observe this vessel alternately to swell and subside, owing not so much, as some have supposed, to the natural flow of the current within it as to the reflux caused by the action of the right auricle of the heart, aided by the hurried and agitated state of the respiratory movements. The difficulty thus occasioned is not only annoying, but sometimes so embarrassing as to render it almost impossible even to see the artery, much less to separate and tie it. To remedy this, it has been suggested that the operation should be suspended for a moment, and the patient placed in the semierect posture, to allow him to make several full and easy inspirations, after which, it is said, the tension of the vein will be diminished, and the regurgitation of the blood cease. The surest and most expeditious plan, however, is to hold the vessel out of the way by means of a broad, blunt hook, or copper spatula, carried down behind the clavicle. In this manner the vein may be effectually compressed to the extent of half an inch, or more, if necessary, and the artery fairly brought into view.

5. The *omo-hyoid* muscle, instead of forming a triangular space, as it usually does, with the scalene muscle and the clavicle, may run parallel with, and just above, that bone, or even entirely below it. In either case, should it be productive of inconvenience to the operator, he should pass a director under and divide it. Such a procedure, however, can seldom be called for, as, by laying open its sheath, the muscle may generally be drawn out of our reach.

6. The *lymphatic glands*, at the inferior part of the neck, may be so much enlarged as to interfere seriously with the different stages of the operation. When this is found to be the case, instead of trying to save these bodies, they should be carefully dissected out, as we shall thus not only expedite our arrival at the artery, but, what is a matter of no little importance, greatly facilitate the healing of the parts after the vessel is tied.

7. Considerable embarrassment may arise from the *condensed and indurated* state of the parts, caused by an effusion of plastic matter. This may always be looked for when the disease is of long standing, or when the tumor is so large as to excite severe inflammation in the deep-seated structures immediately above the clavicle, thereby obscuring the nerves and vessels.

Finally, the position of the *pleura* above the clavicle often presents a very serious impediment to the ligation of the subclavian. The extent of this projection varies, on an average, from an inch and nearly a half to two inches, and sometimes even exceeds the latter measurement. What adds to the embarrassment, especially when the aneurism is very large, is the fact that the artery in the third part of its course runs for some distance in close contact with the pleura, which, in the effort at detaching the vessel, thus incurs great risk of being penetrated, as has, indeed, happened in a considerable number

of cases. The late Dr. Isaacs, of New York, ascertained that the top of the pleura, or that portion which projects above the clavicle, is not always dome-shaped, but that it occasionally forms cul-de-sacs, extending upwards, and sometimes even laterally into the very recesses at the root of the neck.

If, from any of the above causes, it is sometimes difficult to denude the artery, to convey a ligature around it will often be found to be much more so. Indeed, this generally constitutes the most annoying and embarrassing step of the operation. To facilitate this procedure, various mechanical contrivances have been resorted to, some of them so complicated in their character as to be well calculated to enhance instead of diminishing the difficulty. Under ordinary circumstances every indication may be fulfilled with the common aneurism-needle, or even with a common eyed-probe. Whatever mechanical contrivance be employed, the ligature, as a general rule, should be passed from before backwards and from below upwards, as it will be found much easier in this way to prevent injury to the subclavian vein, while there will be no danger whatever of including any of the cords of the brachial plexus of nerves. Owing to the great depth of the wound, not a little difficulty is sometimes experienced in tightening the knot. In this case the ingenious instrument invented by Dr. Hosack, of New York, will be found very useful. By holding the first knot firm, it enables the surgeon to tie a second or third with the utmost facility.

Notwithstanding the assistance to be derived from the different instruments that have been invented for that purpose, such has been the difficulty, in some instances, of conveying the ligature around the artery as to lead not only to great delay, but almost to an abandonment of the operation. It has been suggested under these circumstances, to saw through the clavicle, a proposal to which I can see no objection, provided the shoulder is so much elevated as to offer an almost insurmountable barrier to the passage of the ligature. By this practice, although a compound fracture of the clavicle would be superadded, yet this would be of the most simple kind, while the operation, instead of occupying from one to two hours, as has repeatedly happened heretofore, could be completed in a comparatively short time; the vessel could be much more effectually secured, the risk of wounding the subclavian vein and other important structures would be greatly diminished, and the patient would have a much better chance for recovery.

The great embarrassment that is occasionally experienced in tying the subclavian artery for axillary aneurism, is well illustrated in a case that occurred in the hands of Dupuytren, in which that celebrated surgeon spent an hour and forty-eight minutes in performing the operation, a part of the time, however, being wasted in consequence of the suffering of the patient. The man died of hemorrhage at the end of four days, when it was found that the ligature included one of the large brachial nerves and only half of the artery, which had been perforated with the aneurismal needle. Ramsden tied one of the brachial nerves instead of the artery; White included three nerves in his ligature, and Desault the greater portion of the brachial plexus. The pleura has been repeatedly wounded, and in several cases the aneurismal sac has been penetrated. The subclavian and jugular veins are liable to be injured in attempts to secure this artery.

The subclavian, instead of pursuing its usual course, occasionally passes in front of the anterior scalene muscle, its situation being thus rendered comparatively superficial. Of this anomaly, I have witnessed not less than five examples in dried preparations. Occasionally, again, the artery, on the right side, is situated considerably higher up than usual, arising, not from the innominate, but from a short, stunted trunk in common with the right carotid; while in other cases, it takes its origin from the arch of the aorta, and passes behind the œsophagus, lying deeply in the neck, so as to render it difficult to find it, as in the celebrated case of Mr. Liston.

The arteries which are more particularly concerned in maintaining the collateral circulation after the ligation of this vessel are the suprascapular, transverse cervical, internal mammary, long thoracic, circumflex, and subscapular, the first three being branches of the subclavian, the other three of the axillary. The thoracic artery frequently arises from the aneurismal sac, and is, therefore, liable to be obliterated for some distance in the progress of the disease.

The subclavian artery has been tied several times in the second course of its extent, but the procedure is very difficult, as well as replete with danger, owing to the proximity of numerous important structures, especially the phrenic nerve, jugular vein, pleura, and thyroid axis. The external incisions are similar to those employed for exposing the artery in the other parts of its extent; as soon as the anterior scalene muscle is fully brought into view, a grooved director is carried behind it, and its lower attachment carefully severed from the first rib, the phrenic nerve having previously been placed beyond

the reach of the knife. The top of the pleura, lying close by, must not be wounded in passing the needle. It will thus be perceived that the operation is one of excessive delicacy, requiring consummate anatomical knowledge and skill for its successful execution. The greatest objection, however, to its performance is that the subclavian is obliged to be tied so close to the superior intercostal and deep cervical branches; a circumstance which must necessarily materially interfere with, if not wholly prevent, the formation of a firm and adherent clot.

The manner of exposing and ligating this artery in the first part of its course need not be pointed out, since, from the fact that all the cases in which the operation has been performed have ended fatally, it is questionable whether it should ever be repeated.

Among the most elaborate statistics of ligation of the subclavian artery are those contributed to the eighteenth volume of the Transactions of the American Medical Association by Professor Willard Parker, of New York. They comprise 196 cases, of which 88 were cured, and 107 died, the result in one not being stated. Of 153 cases in which the sex is given, 138 were males and 15 females. The right artery was tied in 82, and the left in 52 cases, in which the side is noticed. The average date of separation of the ligature was the 21st day. In the first portion of its course, it was ligated 13 times, without a single recovery; in the second portion of its course 9 times, with 4 deaths, and in the third portion of its course 174 times, with 89 deaths. In their point of order, the most frequent causes of death were hemorrhage, exhaustion, pyemia, pleurisy, and rupture of the sac. The artery was ligated 57 times, with 21 deaths, for spontaneous axillary aneurism; 24 times, with 8 deaths, for traumatic axillary aneurism; 24 times, with 15 deaths, for spontaneous subclavian aneurism; 5 times, with 3 deaths, for traumatic subclavian aneurism; and 8 times, with 6 deaths, for aneurism of the innominate artery. In the remaining cases the subclavian artery was ligated for other causes than aneurism.

In the collection of Dr. Koch are comprised 185 cases of ligation of the subclavian in the third portion of its course, for all causes. Of these, 100 died, 82 recovered, and in 3 the result is not stated. Ligature between the scalene muscles was practised in 12 cases, of which 7 recovered; in 9 of the operations, for aneurism, and in 3 for other causes.

Dr. Wyeth's tables, published in 1877, embrace an analysis of 283 cases of ligature of the subclavian artery, all, excepting 32, relating to the third surgical division of its course. The sex is given in 262 cases, of which 240 occurred in males, and only 22 in females. The right side was affected in 132 cases, and the left in 90 of the 222 cases in which these particulars are stated. The greatest number of the cases occurred from the twentieth to the fortieth year. Of the 283 cases affecting the three surgical divisions of the artery, 162, or 57 per cent., proved fatal. Hemorrhage after the operation was noticed in 93 cases, in 47 of which it proved fatal. In the majority of cases, in which the fact is stated, the ligature came away between the eleventh and twenty-first days; in one as early as the seventh day, and in one as late as the ninety-sixth day. Of 19 cases in which the subclavian was tied in its first course not one recovered. Of these cases 13 were for ligature of the subclavian alone, and 6 of this artery and the carotid on the right side. In 8 of the fatal cases the cause of death was hemorrhage. From these facts it is evident that, as stated by me in former editions of this work, ligation of this portion of the artery for aneurism on the distal side of the ligature is not a safe or proper operation. Ligation of the subclavian in the second part of its surgical course, behind the scalene muscle, presents 13 cases, of which 4 completely recovered, and 9, or 69 per cent., perished. Of the former cases, in one—that of Morton—gangrene seized on the extremity, and death was averted by amputation at the shoulder-joint. Of ligation of the artery in its third division, that is, from the outer border of the anterior scalene muscle to the lower border of the first rib, the tables give 251 cases, of which 134, or 53 per cent., were lost. Of the 117 recoveries, the great majority were complete. In gunshot and other wounds of the subclavian artery, considered as a whole, the only safe procedure is ligation of the injured vessel at both ends. Experience has proved that, if the artery be tied in its continuity, death from hemorrhage is inevitable.

In a case reported in 1868, by Mr. Turner, of Brighton, that gentleman tied successfully both subclavian arteries, at an interval of two years, for axillary aneurism.

The subclavian is occasionally tied for wounds of the axillary artery. Mr. Guthrie refers to 22 cases in which it was secured for this purpose, 11 times above the clavicle, and 11 times below. Of the former cases, 9 recovered, and two died; death in one being caused by the bursting of an internal aneurism, and in the other by gangrene after

amputation at the shoulder-joint. Of the 11 cases in which the artery was tied below the clavicle, 6 recovered, and 5 perished, three from gangrene of the limb, one from exhaustion, and one from hemorrhage. During our late war this vessel was secured above the clavicle, for a similar object, 17 times, with 2 recoveries ; 13 times after amputation at the shoulder-joint, of which 9 perished ; and twice, with one cure, for secondary bleeding after excision of the humerus. Of 66 cases of ligation of the third portion of the subclavian for hemorrhage from gunshot and other wounds, analyzed by Dr. Wyeth, 19 recovered, and 47 died.

LIGATION OF THE VERTEBRAL.

The vertebral artery is usually the first largest branch of the subclavian, and always bleeds profusely when divided, as it occasionally is in wounds of the neck. Taking the opening as the guide, the vessel should be traced to the seat of injury, and a ligature applied to each extremity. The dissection necessary for its exposure should be conducted with the greatest caution, on account of the important and complex relations which the vertebral sustains to the surrounding parts. The best guide to the seat of the vessel is the transverse process of the sixth cervical vertebra, situated about two inches above the clavicle, and usually known as the carotid tubercle. The artery will be found just below this prominence, deep in the wound, and at the inner side of the anterior scalene muscle.

A case has been reported by Maisonneuve in which he tied successfully the vertebral artery, together with the inferior thyroid, below the sixth cervical vertebra, on account of a gunshot wound. He carried his incision along the anterior edge of the sterno-cleido-mastoid muscle, and exposed the sheath of the common carotid artery, which was then carefully held aside while he denuded and secured the injured vessels. Nuntianti Ippolito has related two cases in which the vertebral artery was successfully tied at its origin. Dr. Smyth, of New Orleans, successfully tied this vessel for secondary hemorrhage after ligation of the innominate and carotid ; and Professor Parker secured it simultaneously with the carotid and subclavian for subclavian aneurism, but the patient died of hemorrhage. Dr. Alexander, of Liverpool, has recently recorded six successful examples of ligation of the left vertebral artery for epilepsy, in one of which the common carotid was simultaneously tied, and in another the internal carotid was consecutively ligated.

When the vertebral artery is laid open in such a manner as to render its ligation impracticable, the hemorrhage may sometimes be promptly and effectually arrested by means of a graduated compress, as in an interesting case treated by Professor Warren Stone, of New Orleans.

LIGATION OF THE INTERNAL MAMMARY.

No instance has been reported, so far as I am aware, of spontaneous aneurism of this artery, but of the traumatic form of the lesion an example has been related by Demontègre as having occurred in a man seventy-six years of age, from the thrust of a sabre. The tumor was two inches in length.

The internal mammary artery is sometimes cut across in gunshot injuries, and it is not unlikely that it might be opened in a bad fracture of the sternum and of the ribs. However this may be, the proper way to secure it, in the event of hemorrhage, is to follow the track of the wound, enlarging it freely, if necessary. The artery with its two veins will be found, in the early part of its course, about three lines from the edge of the sternum, in front of the triangular muscle, which separates it from the pleura. It may readily be reached in the three upper intercostal spaces by a vertical incision, two inches and a half in length, carried in the direction just indicated, successively through the superficial fascia, skin, pectoral, and intercostal muscles ; the deep structures must be divided with great care upon a grooved director, and the artery cautiously separated from its satellite veins. The pleura must not be interfered with. Below these points the operation will be very difficult, if not impracticable, on account of the great narrowness of the intercostal spaces. In case of emergency, the only feasible plan would be to cut away one of the costal cartilages.

LIGATION OF THE INFERIOR THYROID.

The inferior thyroid has been repeatedly tied for hemorrhage and for the cure of goitre. In wounds of the neck, involving this vessel, the ligation is, in general, easily effected simply by enlarging the existing opening in the direction of the part whence the blood issues ; but when there is no such guide, the operation is usually one of considerable difficulty, requiring nice anatomical knowledge and careful dissection.

The inferior thyroid artery, in the first part of its course, ascends a little, and then inclines inwards, passing behind the great vessels and nerves of the neck. The easiest way of exposing it, when there is no wound, is to make an incision along the inner border of the sterno-cleido-mastoid muscle, as in the operation for tying the primitive carotid, the sheath of which should be drawn carefully outwards. The artery will be found to cross over towards the thyroid gland, opposite, in most cases, to the fifth cervical vertebra, and may readily be encircled with a common aneurism-needle. Care must be taken not to injure the sympathetic, recurrent, and hypoglossal nerves. On the left side the artery lies in close contact with the œsophagus and thoracic duct.

LIGATION OF THE AXILLARY.

Deligation of the axillary artery was first performed by Mr. Richard Chamberlaine, of Jamaica, in 1815. The operation is required chiefly on account of penetrating wounds of the chest, secondary hemorrhage after amputation at the shoulder-joint, or the accidental laceration of the vessel during the reduction of ancient dislocations. Of the latter occurrence, a number of cases have been reported by surgical writers. There are two regions where the artery may be secured, either just below the clavicle, or in the hollow of the axilla. In the intermediate point it is so deeply situated, and is in such intricate relations as to render its approach very difficult.

As the artery in the first of these regions is very deep-seated, it has been advised, instead of tying it, to ligate the subclavian in the third stage of its course. Cases, however, occur, in which it is desirable to secure it soon after its origin, and this may generally be done without any difficulty, provided the surgeon is sufficiently cool and collected, and has a thorough knowledge of the anatomy of the parts. The patient being placed in a half-sitting posture, with the arm slightly abducted, an incision is carried along the inferior border of the clavicle, through the skin and platysma-myoid, commencing one inch from the sternum, and extending to within a short distance of the deltoid muscle, care being taken to avoid the cephalic vein, as it lies in the groove between the latter and the great pectoral. The next step consists in dividing the fibres of the great pectoral to the full extent of the external wound. The small pectoral is now seen at the lower portion of the wound, and should be relaxed by bringing the arm close to the trunk. A retractor being inserted, and the divided structures well depressed, the artery will be found at a short distance below the clavicle invested by a dense fascia, which must be carefully scraped through before the vessel can be fairly exposed to view. The accompanying vein, which often swells suddenly out during expiration, lies below and in front of it, while the brachial plexus is behind, except one of its branches, which is above and in contact with it. The anterior thoracic

artery, one of the offsets of the axillary, is also on its anterior surface. The needle is passed from within outwards, in order to exclude the vein. As difficulty is sometimes experienced in distinguishing the artery from the cords of the axillary plexus of nerves, it will be well, before tightening the thread, to ascertain what effect its application has upon the pulse at the wrist, or upon the aneurismal sac. The costo-coracoid ligament sometimes requires division in this operation. The anatomical relations of the artery are well shown in fig. 350, from Erichsen.

Instead of cutting through the substance of the great pectoral muscle, the artery may easily be exposed by carrying the incision along the groove between its two bellies, commencing about one inch external to the sterno-clavicular joint, and extending outwards

and downwards, for at least three inches and a half, in the direction of the insertion of the muscle. If, upon separating the two bellies, it be found that there is not sufficient room, the upper one should be divided perpendicularly as far as the collar-bone. The artery has sometimes been tied in the first part of its course, as in the cases of Desault and Roux, by simply separating the pectoral and deltoid muscles, without any division of their substance.

To expose the artery in its inferior section, fig. 351, from Bryant, the arm should be abducted and supinated, and an incision, nearly three inches in length, made through the

Fig. 351.

Ligation of the Axillary Artery.
axilla, close to the border of the broad dorsal muscle. The connective and aponeurotic structures being next divided, the median nerve and axillary vein will be brought into view, the two roots of the former embracing the artery on each side, and the latter running along its anterior surface. Cautiously separating these with the finger, or the forceps and director, and turning them in opposite directions, the artery is exposed, and tied by passing the ligature from within outwards.

It is barely possible that the axillary artery might require ligation in its second course, as it lies under cover of the small pectoral muscle. If so, the muscle should be divided about three-quarters of an inch from its attachment to the coracoid process. The great objection to the operation is, not the depth of the artery in this situation, but the difficulty of separating it from the axillary plexus of nerves, and the close proximity of the ligature to the origin of the thoracic vessels, thus embarrassing the formation of a firm clot.

Of 15 cases of ligation of the axillary artery for gunshot wounds during the War of the Rebellion only 3 were successful.

LIGATION OF THE BRACHIAL.

The brachial artery, in consequence of wounds and various kinds of traumatic aneurisms, requires to be ligated more frequently than any other artery in the body. Extending from the lower border of the axilla, on a level with the tendon of the teres muscle, to nearly one inch below the bend of the elbow, it is overlapped above by the coraco-brachial muscle and in the middle by the two-headed flexor, while inferiorly it is completely covered by a reflexion of the brachial aponeurosis. Its whole course, however, is comparatively superficial, so that it is easy to feel its pulsations in the greater portion of its extent. In attempting to secure the artery high up, near its origin, an incision, two inches and a half in length, should be made along the inner margin of the coraco-brachial muscle, the limb being extended and supinated with the forearm in a state of partial flexion. The artery, accompanied by its two veins, lies here between the median and ulnar nerves, the former being on its outer side, and the latter on the inner. If the artery is sought for at the middle of the arm, the best guide to its seat will be the ulnar edge of the two-headed flexor muscle. The median nerve, in this part of the course of the artery, is usually on the inside and in front of the vessel, as in fig. 352, from Bryant. At the bend of the arm, the brachial is readily exposed by dividing the brachial aponeurosis in a line with the ulnar border of the tendon of the two-headed flexor muscle, as in fig. 353, also from Bryant. In none of these operations is it necessary to divide any muscular fibres.

In operating upon the brachial artery, it should be borne in mind that this vessel is subject to certain varieties, which may serve both to perplex the surgeon, and mar the result of the undertaking. The most frequent of these anomalies is the high division of

Fig. 352.

Ligation of Brachial Artery.
the artery into the radial and ulnar, which, on reaching the elbow, either pursue their usual course, or, as is more generally the case, the former proceeds superficially down the forearm, while the latter becomes deep-seated; or their course may be reversed, the radial following its ordinary route, while the ulnar descends immediately under the skin. Sev-

Fig. 353.

Ligation of Brachial Artery.
eral instances have been met with in which the brachial divided high up into two branches, which subsequently united into a single trunk, which afterwards bifurcated regularly into the radial and ulnar.

During the War of the Rebellion the brachial artery was ligated for hemorrhage consequent upon gunshot injuries 76 times, with a result of 55 recoveries and 21 deaths. In 9 cases consecutive amputation was practised, and only 3 recovered.

LIGATION OF THE RADIAL, ULNAR, AND PALMAR ARTERIES.

The radial artery, whose course along the forearm is indicated by a line drawn from the middle of the bend of the elbow to the forepart of the styloid process of the radius, may be tied near its origin, at its middle, and at its inferior extremity. When the design is to ligate it above, or in the first of these situations, it may be approached by an incision, about three inches in length, parallel to the inner border of the long supinator muscle, between which and the round pronator the vessel will be found, accompanied by its two veins, the radial branch of the musculo-spiral nerve lying at its outer side, and some distance from it. Care is taken not to wound the basilic vein. In the middle third of the forearm, the artery lies between the long supinator and flexor muscle of the carpus, the radial nerve descending close along its radial border, as in fig. 354, from Bryant. In the inferior portion of its extent, the artery is comparatively superficial; its pulsation is very distinct in the greater part of its length, and thereby serves as a ready guide to its course. The artery, as it lies upon the back of the carpus, underneath the tendons of the extensors

of the metacarpal bone and first phalanx of the thumb, is easily reached by an oblique, transverse, or longitudinal incision. It is accompanied by two veins.

The ulnar artery is sometimes divided in the upper part of its extent by a knife or ball, and may then generally be easily found by taking the wound as our guide, enlarging it, if necessary, and tying the vessel at each extremity. When a false aneurism exists in this situation, it is usually recommended to ligate the brachial, but I am satisfied that it

Fig. 354.

Supinator longus
Ligation of Radial Artery.

would be more safe, in every instance, to tie the ulnar soon after its origin, by cutting boldly through the thick muscular mass at the upper third of the forearm, as we could thus effectually guard against hemorrhage from the recurrent circulation. In the middle of the limb the artery lies along the radial border of the ulnar flexor of the carpus, which should, therefore, be taken as a guide to the knife, and be carefully separated from the common flexor of the fingers. The ulnar nerve here lies on the inner side of the vessel. Near the wrist the artery is generally found with facility, its situation being indicated by its pulsation.

During the War of the Rebellion the ulnar artery was ligated 10 times, with 3 deaths, and the radial artery 20 times, with 4 deaths.

Ligation of the palmar arteries is rendered necessary in case of external injury, and can only be successfully effected by enlarging the wound freely upon a grooved director. This should always be done as early as possible, before the supervention of swelling, which greatly increases the difficulty. When the parts are much obscured, acupressure will sometimes arrest the bleeding more readily than the ligature.

The superficial palmar artery, forming what is called the palmar arch, is the continuation of the ulnar artery, and lies, at its commencement, on the annular ligament of the wrist, and then on the tendons of the superficial flexor of the fingers, in close relation with the divisions of the median and ulnar nerves. It is covered near the inner border of the hand by the short palmar muscle, and afterwards by the palmar aponeurosis and the integument. At the thumb it inosculates with a small branch of the radial artery. The deep palmar artery arises from the ulnar artery at the origin of the palmar arch, a little beyond the pisiform bone, and, passing forward under cover of the short flexor of the little finger, unites with the palmar termination of the radial artery, thereby completing, as stated by Quain and Sharpey, the deep palmar arch.

LIGATION OF THE ABDOMINAL AORTA.

Ligation of the abdominal aorta may be required on account of a wound, either of itself or of the common iliac, and in that event the best plan would probably be to enlarge the external opening to an extent sufficient to encircle the vessel with the thread. In ligating the vessel for aneurism, the patient should lie on his right side, and care should be taken to avoid injury to the peritoneum, which can easily be done by adopting the procedure of Dr. Murray, since followed by Monteiro and South, of making a curvilinear incision with the convexity towards the vertebræ, from an inch above the anterior superior spinous process of the ilium to the cartilage of the tenth rib, as in fig. 355, from Bryant. It should be fully six inches in length, and should extend, in the first instance, merely through the common integument. The various underlying structures should then be severally divided until the peritoneum is brought into view, which is cautiously peeled off from the iliac and psoas muscles with the hand a short distance beyond the contemplated point of ligation. The separation of the aorta from its accompanying vein on the right

side, and the filaments of the sympathetic nerve in front, constitutes one of the greatest difficulties of the operation, and is generally best effected with a long director, slightly

Fig. 355.
Ligation of the Aorta.

sharp at the extremity, and the nail of the index finger. The ligature should be passed around the artery from left to right, and from behind forwards, about one inch above its bifurcation into the common iliacs.

LIGATION OF THE COMMON ILIAC.

The common iliac artery was first ligated by Dr. William Gibson, of this city, in 1812, in a case of gunshot wound. His patient died in thirteen days, of peritonitis and secondary hemorrhage. In 1827 it was tied, for the first time, for aneurism, by Dr. Mott. The disease occupied the external iliac artery; the ligature came away on the nineteenth day; and in less than two months the man was entirely well.

This artery has been secured 65 times, with a result of 14 recoveries and 50 deaths, the issue in 1 being unknown; 36 of the operations were for aneurism, of which 10 were successful, and 25 died, the result being undetermined in 1; 16 were practised for hemorrhage, with 15 deaths; 4 were for malignant pulsating tumors, of which 3 died; 2 were for arterio-venous aneurism of the external iliac artery and vein, and both were fatal; 1 was for anastomotic aneurism, and the patient, a child six weeks old, recovered; and in 6 the nature of the disease is unknown, but 5 died. The mortality of the procedure, based upon 64 cases in which the result is known, is, therefore, 78.15 per cent. Three fatal cases occurred in the army during our late war.

Fig. 356.

Ligation of the common iliac, fig. 356, is far from being an easy operation, especially in case of aneurism, attended with a large tumor and morbid adhesions of the peritoneum. The patient lying on his back, with the thighs somewhat relaxed, a slightly curvilinear incision is made along the lower part of the abdomen, about half an inch above Poupart's ligament, commencing at the external ring and passing upwards and outwards a short distance beyond the anterior superior spinous process of the ilium, its length varying from five to seven inches, according to the exigencies of the particular case. The operator should, in every instance, give himself an abundance of room. The first cut extends merely through the skin and superficial fascia. The other

Ligation of the Common Iliac.

structures, beginning with the aponeurosis of the external oblique muscle, are then sever-
ally divided upon the director down to the peritoneum, more and more caution being
observed in proportion as we approach the deeper parts. The serous membrane is now
gently and slowly detached, by means of the finger, from the aneurism and other textures,
as high up as the necessities of the case may demand. The artery being thus denuded,
is next isolated from the accompanying vein, and the thread deposited by passing the
needle from within outwards, above the middle of the vessel. The different steps of the
operation will be greatly facilitated if the patient has previously taken an active cathartic,
to unload the bowels. Care must be employed not to wound the spermatic cord.

From numerous trials upon the dead subject, Dr. Stephen Smith advises, as the easiest
and safest method of approaching the vessel, that an incision be made extending from near
the anterior extremity of the eleventh rib to within a few lines of the internal ring, with
a sharp curve inward of one inch. It will thus pass about an inch and a half within the
anterior superior spinous process of the ilium, and be about seven inches in length. The
curve at the lower extremity of the wound will allow the most perfect freedom in the
elevation of the peritoneum, and the complete exposure of the artery.

In a case reported by Professor Sands, of New York, in 1881, the incisions were made
directly down to the artery, through the peritoneum in the linea alba. The operation,
which was performed with the carbolized catgut ligature under antiseptic precautions, was
followed by gangrene of the foot and leg, requiring subsequent amputation of the thigh.
Notwithstanding these untoward occurrences, the intemperate habits of the patient and
a syphilitic taint of the system, complete recovery took place.

The primitive iliac arteries extend from the cartilage between the fourth and fifth
vertebræ to the sacro-iliac symphyses, diverging from each other as they descend at a
somewhat acute angle, their point of commencement being nearly one inch and a half
below the umbilicus. Each rests on the spine and psoas muscle, and is crossed anteriorly,
at its bifurcation, by the ureter. On the right side, the accompanying vein lies, above,
behind and external to it, while, lower down, a portion of the vein appears on the inner
side; on the left side, the vein passes along the inner side of the artery, both vessels being
placed under cover of the sigmoid flexure of the colon. The course of the artery is indi-
cated by a line extending from the umbilicus to Poupart's ligament, a little nearer to the
pubes than to the ilium.

The length of the common iliac artery is generally about two inches, from which it
varies from less than twelve lines as the minimum to three inches and a half as the
maximum, depending, as has been shown by Mr. Luther Holden, either upon a high
division of the aorta, or a low division of the common iliac, or both. It is often short in
tall men, and conversely. Both vessels are usually of the same length.

LIGATION OF THE INTERNAL ILIAC.

The ligation of the internal iliac has now been practised twenty-six times, the operators
having been Altmüller, Arendt, Atkinson, Bigelow, Cianflone, Coluzzi, Galozzi, Higgin-
son, Kasinski, Kimball, Landi, McKee, McLean, Morton, V. Mott, A. B. Mott, Oeverent,
Porta, Stevens, Syme, Thomas, Thompson, Torracchi, Tripler, and White, the remaining
case having occurred in Bellevue Hospital. It was first performed by Dr. Stevens, of St.
Croix, in 1812, upon a negress, for what was supposed to be an aneurism of the gluteal
artery, but which was found, on dissection, three years afterwards, to have arisen from
the sciatic. The tumor had originated spontaneously, and was, at the time of the opera-
tion, of the volume of a child's head. Of the 26 cases, 8 terminated successfully, and 18
fatally, a result which need not create surprise when we take into consideration the great
depth at which this vessel is situated, the injury that must necessarily be inflicted upon
the surrounding parts in exposing it, and the exceedingly unfavorable character of most
of the cases themselves prior to the operation. The artery, moreover, is very short and
disproportionately large, being generally less than two inches in length; it is, besides,
in intimate relation with various important structures, thus rendering it extremely difficult
of access. Thus, it lies on the internal iliac vein, which, however, on the right side,
projects from underneath it over its outer edge; it is crossed above by the ureter, and is
overhung by the bladder, while that on the left side lies immediately behind the rectum.
Close by are the sacro-lumbar and obturator nerves, the latter, along with the external
iliac vein, running in the angle which separates the internal from the external iliac artery.

The manner of exposing the artery is the same as in ligating the common iliac. Dr.

White, of Hudson, who tied this vessel successfully in 1827, for gluteal aneurism, made a semicircular incision on the side of the abdomen, with its convexity to the ilium, seven inches in length, commencing two inches to the left of the umbilicus, and terminating close to the external ring. It is not necessary, however, I conceive, to carry the incision so far inwards, as the object may be just as well attained by the other procedure, and with less risk of bad consequences. The peritoneum is carefully raised with the fingers, and it is worthy of notice that the membrane, as it is being peeled off, invariably carries with it the ureter, thus placing this duct completely beyond the reach of the ligature. The fascia investing the artery is scraped away with the nail or handle of the scalpel, and, taking the precaution of avoiding the external iliac vein, as it lies in the angle between the internal and external iliac arteries, the surgeon deposits the ligature by passing the needle from within outwards.

When the internal iliac artery is very short, or the pelvis unusually small, so as to render the ligation of the vessel very difficult, it would be more prudent to secure the common trunk ; the procedure would be attended with less violence to the parts, and with less risk of peritonitis and secondary hemorrhage.

The most common cause of death after this operation is secondary hemorrhage, of which one of the patients perished within the first twelve hours. In Mott's case, a successful one, the peritoneum was opened. One of the difficulties of this operation, is the separation of the iliac artery from its accompanying vein. The circulation, after the application of the ligature, is carried on mainly by the lumbar and sacro-lateral branches.

LIGATION OF THE GLUTEAL.

The gluteal artery has been repeatedly ligated on account of hemorrhage and traumatic aneurism, as, for example, in the famous case of Mr. John Bell, where, to use his own hyperbolical language, the incision was upwards of a foot and a half in length. In exposing the vessel for the relief of hemorrhage, the surgeon is necessarily obliged to take the external wound as his guide, enlarging it, if possible, in the direction of the muscular fibres, and giving himself an abundance of room, especially if the artery is divided just as it emerges from the sacro-sciatic notch. It must be remembered that the vessel is accompanied by a vein and nerve, which must be carefully excluded from the ligature. If the artery is cut off close, it may be necessary to pass the thread with a curved needle, and to include in the noose some of the surrounding tissues, as it will probably be impracticable to raise it with the tenaculum.

In case of traumatic aneurism of this artery, most writers recommend the ligation of the internal iliac ; but, when we remember the difficulties and dangers of this operation, and the probable occurrence of peritoneal inflammation and of secondary hemorrhage, it seems to me that it would be better, in every respect, to cut down upon and tie the gluteal itself. The operation, will, of course, be bloody and formidable, but skill, boldness, and promptness may accomplish much, even in a case like this, especially when everything is well ordered beforehand, and the assistants are properly instructed in their respective duties. The incision, made in the direction of a line extending from the posterior superior spinous process of the ilium to a point midway between the tuberosity of the ischium and the great trochanter, must be at least eight inches in length, and should be carried at one stroke down into the aneurismal sac, the contents of which should then be turned out, and the artery instantly secured, as it lies towards the upper part of the wound.

When ligation is impracticable, on account of the great shortness of the artery, the hemorrhage may sometimes be effectually arrested by means of a graduated compress, thrust into the bottom of the wound, previously cleared of clots, and firmly bound down by a roller carried around the thigh and pelvis.

In a case of traumatic aneurism of the gluteal artery, in a boy, fourteen years of age, Professor Campbell, of Montreal, in 1862, secured this vessel at the upper and anterior portion of the sciatic notch, without opening the tumor. Some difficulty was experienced in passing the ligature, but as soon as this was tied all pulsation in the sac ceased, and a rapid recovery was the consequence.

In 1834, Mr. Richard Carmichael, of Dublin, reported a case of wound of the gluteal artery in a youth, seventeen years of age, in which he made an incision, five inches in length, into the sac of the aneurism, turned out from one to two pounds of coagulated blood, and ligated the vessel, the patient making a rapid recovery. In a similar case, Mr. Syme, after having evacuated the contents of the tumor, passed a double thread under the artery, and tied it on both sides of the wound, the bleeding of which was effectually

controlled by the pressure of the finger. The operation was completely successful. In 1877, Mr. Edward L. Hussey, of Oxford, tied the large descending branch of the gluteal artery on account of an aneurism, the result of a punctured wound. The sac was laid open by a large incision. Death occurred on the sixteenth day from secondary hemorrhage. Of five cases of ligation of the gluteal artery for hemorrhage during the War of the Rebellion, two recovered, and three died.

LIGATION OF THE SCIATIC.

The sciatic artery is also liable to be injured, either by sharp-pointed bodies penetrating the gluteal region, or by falls upon the buttock in which the vessel is laid open by a splinter of bone around which it passes as it proceeds forwards. It is situated under the great gluteal muscle, at first posterior and then internal to the great sciatic nerve, and winds around the spinous process of the ischium, near its root, behind the muscles which are inserted into the intertrochanteric line of the femur. It may be exposed by making a similar incision, as in the preceding case, but about an inch and a quarter lower down. When the operator is in doubt as to which artery is implicated, whether the sciatic or gluteal, the incision should be made as nearly as possible in the intermediate space.

The sciatic artery has been tied, in at least one instance, for an aneurism seated upon its own trunk, Dr. Dugas, of Georgia, being the operator. Owing, however, to secondary hemorrhage, caused, apparently, by the patient's own imprudence, the common iliac had to be secured at the end of a week, when the man was almost moribund from the loss of blood. Death occurred four days afterwards. Both of the cases in which this vessel was tied, during our late war, died.

LIGATION OF THE EXTERNAL ILIAC.

Ligation of the external iliac artery was first practised by Mr. Abernethy, in 1796, in a case of aneurism of the femoral artery, which he had previously tied at the distal side of the tumor; but severe hemorrhage coming on some time after, he found it necessary to apply a ligature above the swelling. The operation, however, failed; and it was not until 1806, after two other attempts, that his efforts were finally crowned with success. In this country it was first performed by Dr. Dorsey, of this city, in 1811, in a case of inguinal aneurism.

Fig. 357.
Ligation of the External Iliac by Abernethy's Operation, modified.

There are several methods in vogue for exposing this artery and encircling it with a ligature, each of which has its advantages and disadvantages, although the results have perhaps not essentially varied in any. That of Abernethy, slightly modified, shown in fig. 357, from Erichsen, is, perhaps, the most unexceptionable. It consists in making a curvilinear incision, with the convexity downwards, along the inferior portion of the abdomen, commencing about an inch and a half above Poupart's ligament, just outside of the external ring, and terminating on a level with the anterior superior spine of the ilium, about two inches on the inner side of this process. Its length should be from three inches and a half to four inches, according to the size of the tumor and the stature of the patient. The first cut, extending through the skin and superficial fascia, will probably sever a few little arteries that should be tied before proceeding any further. The aponeurosis of the external oblique muscle is now in sight, and should be divided upon the director. Then comes the internal oblique muscle, next the transverse muscle, and, finally, the transverse fascia, readily recognized by its opaque, whitish appearance. A small hole having been scratched into this membrane with the nail or scalpel, it is slit open to the full extent of the outer

wound.   The next step, and one of the most delicate of all, consists in gently and cautiously detaching the peritoneum from its connections in the iliac fossa; an operation which is often attended with considerable difficulty on account of the morbid adhesions.   The iliac artery will now be felt pulsating at the bottom of the wound, having the anterior femoral nerve at its outer side and on a somewhat deeper plane, and the iliac vein at first behind, but afterwards, near Poupart's ligament, internal to it.   The sheath of the artery is now carefully penetrated, when the instrument bearing the ligature is gradually insinuated around the vessel from its inner side, this procedure being found best to avoid injury to the vein.   The course of the artery is indicated by a line extending from the umbilicus to a point midway between the pubic symphysis and the anterior superior spinous process of the ilium.

Arendt has placed upon record a case in which he successfully tied both the external iliacs in the same patient after an interval of only eight days.   In a similar case in the hands of Mr. Tait, of London, the interval was upwards of eleven months; and in another, in the practice of Dr. Watson, of Glasgow, the interval was nearly nine months.   Mr. Newbiggin, in a remarkable instance, by tying the external iliac artery, cured both an inguinal and a popliteal aneurism at the same time.

There are several circumstances worthy of attention in connection with the ligation of the external iliac.   In the first place, the ligature should, if possible, be placed around the vessel about its middle, which will be nearly two inches above Poupart's ligament, the artery being usually from three inches and a half to four inches in length.   If the ligature is applied low down, near to the origin of the epigastric artery, there may not be sufficient room for the formation of a coagulum, and the patient may perish of secondary hemorrhage, as happened in a case recorded by Béclard.

Secondly, if the transverse fascia be not properly divided there will be danger in peeling off the peritoneum of detaching the iliac fascia along with it, and so dragging the artery out of its normal position to such an extent as to cause, perhaps, serious embarrassment in finding it.

Thirdly, care must be taken not to wound the peritoneum.   I have witnessed several instances in which it was separated with immense difficulty, on account of the great firmness with which it adhered to the aneurismal sac, from the effects of plastic deposits.   In a case of Dr. Wright Post, of New York, the membrane was so much thickened and altered by disease that he found it impossible to detach it, and was consequently obliged to make an opening into it in order to admit the ligature.   Both in this case and in one in the practice of Mr. Tait, the patient recovered.

Fourthly, no little difficulty is occasionally experienced in separating the artery from its accompanying vein, owing to their naturally firm union, which is often greatly increased by disease.   The object is most easily attained with a grooved director slightly sharpened at the extremity.   In passing the ligature, care must be taken not to include the genital branch of the femoral nerve.

Fifthly, should the external iliac be found to be too much diseased, or the tumor so large as to overlap the greater portion of the artery, as it may when the sac extends upwards beneath Poupart's ligament, it will be easy to ligate the common trunk simply by enlarging the wound, especially at its upper angle.

Sixthly, the manipulations will be greatly facilitated if the patient's bladder and bowels are well evacuated a short time previously to the operation.

Seventhly, the ligation of this artery is sometimes rendered very difficult on account of the presence of an inguinal hernia, as in a case in the practice of Mr. Morgan, of London.   Should such a contingency arise, unusual caution must be exercised, otherwise the bowel may be opened.

Lastly, the wound made in the operation should in this, as in the ligation of the other pelvic arteries, be sewed up carefully from the bottom, by carrying the needle close down to the peritoneum; in other words, the muscular and integumental lips should be tacked together separately, the object being the production of firm union, so that there may be no risk of hernia when the patient begins to set up and walk about.

The tables of Dr. Norris and Dr. Cutter show that this vessel has been tied for all causes 155 times, with 47 deaths, 17 having perished of gangrene, 3 of sloughing of the sac, 9 of hemorrhage, 5 of peritonitis, 3 of exhaustion, 2 of tetanus, and the remainder of various other affections.   During our late war our army surgeons had 16 deligations of this artery, with only 2 recoveries.

This artery is sometimes tied on account of external injury.   The operation, however, is seldom successful, owing to the violence inflicted upon the peritoneum.   In a case of

wound from an accidental stab, in a lad seventeen years of age, the bleeding was temporarily arrested by compresses, until Velpeau placed a ligature around the vessel. The patient made a speedy recovery.

After the ligation of the external iliac, the collateral circulation is maintained chiefly by the anastomosing branches of the gluteal, sciatic, obturator, and pudic arteries with the circumflex and deep branches of the femoral.

LIGATION OF THE EPIGASTRIC.

The epigastric artery is occasionally wounded, either accidentally or in operating for hernia, tapping the abdomen, or ligating the iliac. The vessel, although small, may give rise to fatal hemorrhage, the more readily as the bleeding is generally insidious and deep-seated, and it should, therefore, be secured without delay. To do this, an incision, about two inches in length, is made just above, and parallel to, Poupart's ligament, in a line corresponding with its centre, cautiously dividing the parts until the artery is reached, as it lies between the transverse fascia and peritoneum. It is accompanied by two veins, which must be carefully excluded from the ligature. The artery arises on the inner side of the external iliac, about three lines above Poupart's ligament, and ascends inwards just within the inner border of the internal ring, where the deferent duct hooks around it on its way to the inguinal canal. Should the vessel be cut off close to the external iliac, it might become necessary to cast the thread round this artery instead of the epigastric.

LIGATION OF THE CIRCUMFLEX ILIAC.

The circumflex iliac artery, given off by the external iliac, usually a little lower than the epigastric, is sometimes wounded, and may, from its large size, cause embarrassing, if not fatal, hemorrhage. It may be secured, in the first part of its course, in the same manner, very nearly, as the epigastric, the incision being made close to, and parallel with, Poupart's ligament, its centre being opposite the internal ring. Further out, it may be exposed by dividing the tendon of the external oblique muscle within half an inch of the margin of the ilium, where it is firmly bound down by the transverse fascia.

LIGATION OF THE COMMON FEMORAL.

The common femoral artery begins on a level with Poupart's ligament, and terminates from an inch and a half to two inches below in the superficial and deep femoral, the former being its direct continuation. The vessel, in all this course, is perfectly superficial, being covered merely by the skin, fascia, and aponeurosis; it is involved, however, in a number of lymphatic glands, which, when enlarged, may receive the pulsation of the artery, and so simulate aneurism. The femoral vein lies on the inside of the vessel, in the same sheath, and great care is required in separating it previously to passing the ligature. The femoral nerve lies external to the artery, and is, therefore, not endangered in the operation. Exposure of the artery is easily effected here by a vertical incision two and a half to three inches in length. The aneurismal needle should be conveyed from within outwards. The saphenous vein, which lies in close proximity to the artery, must not be wounded.

The late Professor W. H. Porter, of Dublin, who secured this vessel three times, made an oblique incision instead of a vertical one, six lines below and parallel with Poupart's ligament, its length being about one inch and three-quarters. Although the operation, when thus performed, is sufficiently easy, I should give a decided preference to the vertical incision, as it admits of more ready access to the artery, as well as of its more easy separation from the accompanying vein, especially in the event of any considerable enlargement of the lymphatic glands.

Great objection has been urged against the ligation of this vessel, in any portion of its course, on account of the liability of the operation to be followed by secondary hemorrhage, it being alleged that no permanent clot can form above the site of the ligature, in consequence of the close proximity of the epigastric and circumflex iliac arteries. One writer, Mr. Erichsen, indeed, declares that the operation should be banished from surgery. Others, on the contrary, assert that there are cases in which it may be very proper, an opinion with which my own views entirely coincide. When secondary hemorrhage arises, it will generally be found that it is due rather to a diseased condition of the coats of the vessel than to the vicinity of large collateral branches. Mr. Porter tied the common

carotid artery within a quarter of an inch of the innominate, and the patient recovered. Mr. Key successfully ligatured the subclavian artery close to the deep cervical; Dr. Bellingham, of Dublin, with an equally fortunate result, tied the external iliac near its root, on account of an aneurism of this vessel; and in his case of deligation of the common femoral, Mr. Oliver Pemberton cast the thread just above the origin of the profunda, the artery, notwithstanding this, being firmly plugged above and below. His patient, moreover, was generally diseased, and sixty years of age. Other cases, of a similar character, might be adduced, but these are quite sufficient to prove that the immediate vicinity of a large collateral vessel is no hindrance to the formation of a solid, substantial clot after the application of a ligature, provided the artery is free from disease, as chronic inflammation, and calcareous, fatty, or amyloid degeneration. I have myself in one instance succeeded in obtaining a firm clot in less than forty-eight hours after the application of a ligature to the femoral artery according to the method originally practised by Mr. Porter, the pressure being taken off completely by the end of that period. In a case in which I exposed the vessel by a vertical incision, fatal hemorrhage set in at the end of the ninth day, owing to a diseased condition of the artery, no protective coagulum having formed.

The number of cases in which this artery has been ligated for aneurism is, so far as I have been able to ascertain, eight, with a mortality of only two, or 25 per cent., a result that ought to satisfy the most exacting statistician. The case of Mr. Collis, usually quoted as one of deligation of the common femoral, is excluded from the accompanying table, since it was not an example of the operation at all, the ligature having been placed just below the profunda, which was given off high up, and the patient dying of secondary hemorrhage. Excluding the case of Mr. Gelston and my last case, in both of which the artery was extensively diseased, it will be perceived that the operation was uniformly successful when the artery was sound. It is true, in two instances, secondary hemorrhage supervened, but it was easily commanded by pressure, while the bleeding in the fatal cases was so alarming as to require deligation of the external iliac in one and acupressure of that vessel in the other. The common femoral trunk has been ligatured several times on account of external injury or for hemorrhage after amputation of the thigh, but the results have not been gratifying.

Date.	Operator.	Disease.	Result.	Remarks.
1848	W. H. Porter	Popliteal aneurism	Recovery	
1849	W. H. Porter	Femoral aneurism	Recovery	
1850	G. H. Porter	Femoro-popliteal aneurism	Recovery	Hemorrhage on 25th day, or five days after separation of ligature, commanded by slight pressure.
1860	J. Smyly	Popliteal aneurism	Recovery	Slight hemorrhage on 11th day, or four days before separation of ligature, easily controlled by pressure.
1868	T. G. Gelston	Femoro-popliteal aneurism	Died	Hemorrhage on 15th day, controlled by ligation of external iliac. Successive hemorrhages from old wound; death from pyemia and gangrene of foot and leg. Femoral artery extensively diseased at site of ligature.
1868	S. D. Gross	Femoral aneurism	Recovery	Pressure of ligature taken off in 48 hours.
1870	S. D. Gross	Aneurismal varix of femoral vessels of stump	Died	Hemorrhage on 6th day, from detachment of ligature, controlled by acupressure of external iliac and distal end of femoral. Patient never rallied. The femoral artery was much dilated and thinned.
1870	O. Pemberton	Femoral aneurism	Recovery	Ligature separated on 40th day. Death from inanition ten days subsequently.

In all the recorded cases in which this artery has been secured for aneurism, except in a single one by myself, the operator did not act from choice, but from necessity, the superficial femoral being inaccessible on account of the situation of the tumor. In the exceptional instance here referred to, the artery was included in a silver wire, loosened in less than forty-eight hours after its application, all pulsation in the aneurism having ceased before the expiration of that period.

LIGATION OF THE SUPERFICIAL FEMORAL.

Ligation of this artery is often necessary on account of wounds involving its continuity, and, until a comparatively recent period, it was almost exclusively practised for the cure of popliteal aneurism. If the artery is severed by a cut, or pierced by a sharp-pointed body, it is evident that it should be secured at the site of injury, the wound being, if necessary, enlarged, and a ligature applied to each extremity of the vessel.

In aneurism, the artery may be tied at two points of its extent, the superior and middle, the former being, however, by far the more eligible, as the vessel here is comparatively superficial, and, therefore, easy of access. Its course along the thigh is indicated by a line extending from a quarter of an inch within the centre of Poupart's ligament to the inner margin of the patella. In the upper third of the limb, it lies immediately beneath the skin and aponeurosis, its pulsation being easily felt as it runs along the inner margin of the sartorius muscle. This space is from four to five inches in length, and is of a triangular shape, its base being formed by Poupart's ligament above, and its apex by the convergence of the sartorius and adductor muscles below. The femoral vein descends along the inner border of the artery, and is inclosed in the same sheath; the connection between them is very firm and intimate, and it, therefore, requires great caution to effect their separation. The femoral nerve lies on the outside of the artery. It is worthy of remark that the moment a ligature is tightened around this artery in any portion of its course, the patient, unless fully anæsthetized, experiences great pain, not unfrequently accompanied by a sense of numbness and tingling in the limb. This effect is probably due to the inclusion of a minute nervous filament, and generally promptly disappears of its own accord.

Fig. 358.
Ligation of External Iliac and Superficial Femoral Arteries.

To expose the artery in this part of its course, an incision should be made along the inner border of the sartorius muscle, beginning about two inches and a half below Poupart's ligament, and extending obliquely downwards to the inferior extremity of the

triangle through the skin and superficial fascia. A portion of the aponeurosis is now pinched up with the forceps, and a horizontal opening made into it barely large enough to admit the point of a grooved director, upon which the sheath of the vessel is carefully divided for about nine lines. The artery is separated from the vein in the usual manner, but with extreme caution, and the ligature passed from within outwards, close to the former vessel. Injury to the vein would be a serious calamity, as the patient might perish from phlebitis, or gangrene of the limb. The occurrence is usually denoted by a gush of black blood upon drawing out the thread. Pressure will readily arrest the flow, and the vessel must on no account be tied, as such a procedure would inevitably give rise to a bad form of suppuration, the ligature acting very much as a seton, exciting and keeping up morbid action. A little nerve occasionally runs down in front of the artery, and must be drawn out of the way.

The femoral artery, in its middle course, as seen in fig. 358, from Bryant, is deep-seated, lying under cover of the sartorius muscle, which must, consequently, be turned to one side in the act of exposing it. The corresponding vein will be found external to the artery. In some instances it is double, and then the artery runs between the two vessels, closely hugged by them; or one of the veins lies in front of the artery and the other in the usual position. In operating upon the superior portion of this space, just below the triangle above described, the incision should be made along the inner edge of the sartorius, which is then everted so as to afford free access to the vessel as it lies beneath the aponeurosis. If, on the other hand, the lower site be selected, the cut should be made on the outside of the muscle; but no one will be likely to do this if he can avoid it, as the operation will be both tedious and difficult, and possesses no advantage whatever over the more common procedure.

The femoral artery is subject to certain anomalies which should not be forgotten when we undertake its ligation, as they might seriously affect the result. The most important of these anomalies are the following:—First, the high division of the artery, the vessel separating a short distance below Poupart's ligament into two branches, which go to form the posterior tibial and peroneal. Secondly, the artery may be double, the supernumerary one giving off the branches usually furnished by the profunda. Thirdly, it may consist of two equal trunks which afterwards unite to form the popliteal. Sir Charles Bell found this curious anomaly in a negro upon whom he operated for popliteal aneurism, the two vessels coalescing as they entered the ham. In this case the blood in the sac had in a great measure coagulated, notwithstanding that the circulation through it had been maintained by the non-ligated artery. A similar instance occurred to Sir Astley Cooper. An abscess formed in the sac, after the detachment of the ligature, and the patient died of hemorrhage. The dissection showed that a large branch had been given off by the femoral artery above the point of ligation, and had again united with that vessel just before it terminated in the popliteal, thereby feeding the tumor, and preventing its obliteration. Mr. Fleming, of Dublin, in 1866, met with a case of double femoral artery, in which he was obliged to secure each vessel separately before any decided impression could be made upon the pulsation of the tumor, an aneurism of the popliteal artery. Matters progressed favorably for some time, when, suddenly, an abscess formed in the sac, necessitating amputation of the limb. Several examples of entire absence of the superficial femoral artery have been recorded, one, among others, by Mance, its place having been supplied by the sciatic, which passed down along the back of the limb to become the popliteal. The femoral vein is occasionally, although rarely, double.

One of the most serious accidents incident to ligation of the femoral artery, for the cure of aneurism, is the puncture of the femoral vein, especially liable to occur, if the greatest caution be not exercised, in the upper portion of the thigh, in consequence of the abnormal adhesions which occasionally form between the two vessels from inflammatory deposits caused by an extension of irritation from the tumor. The injury may be inflicted with the knife in the efforts to separate the two vessels, or with the aneurism needle in the act of passing the ligature. However this may be, the artery must at once be exposed either higher up or lower down, and the wound in the vein treated by compression, so as to convert it into one of a simple character. If, as when the vein is transfixed with the needle, the ligature be left in the vessel, it will inevitably act as a seton, lighting up diffuse phlebitis, speedily followed by the death of the patient. All such accidents are sure to end fatally; indeed, even the mere wounding of the femoral vein is always a very serious occurrence. It remains still an open question whether, when the vessel is merely pricked, it would not be perfectly safe to include the edges of the opening in a delicate

ligature, as has repeatedly been successfully done in perforation of other veins, provided the operation do not interrupt the current of blood in the injured vessel.

Another accident of a very embarrassing nature, and one which has occurred to me on two occasions, sometimes arises in ligating the femoral artery. I allude to a welling up of blood in the wound either before or after the ligature has been passed, evidently due to the division of a small anomalous branch, given off by the femoral, and unavoidably opened in separating the vessel from the surrounding structures. The bleeding is very embarrassing, the blood filling the wound as fast as it is sponged out; and in the two cases adverted to I was obliged to tie the main artery above and below the anomalous branch, inasmuch as it could not be included in a ligature.

The tables of Dr. Norris show that this artery has been tied for all causes 204 times, with 50 deaths, the mortality being about one in four.

Compression of the femoral artery is often necessary on account of hemorrhage, either of this vessel itself, or of some of its branches. It is also frequently employed for the purpose of controlling the circulation of the limb in amputations of the thigh and leg; and latterly it has been much resorted to for the cure of popliteal aneurism, having, in many cases, superseded the use of the ligature. When the object is to arrest the flow of blood, or stanch hemorrhage, the most suitable point for its application is the margin of the pubic bone, which is separated from the artery only by the pectineal muscle, and upon which, consequently, the pressure may be made with great efficiency. The best instrument for the purpose is the thumb of a stout assistant, or the handle of a large key, resting upon a small, thick pad. The more concentrated the pressure is, the more efficacious it will be in stopping the bleeding, and in preventing injury to the accompanying vein and nerves, circumstances that must not be overlooked in such a procedure. If the force be applied with the thumb, it may often be maintained, for several successive days by a relay of assistants, without detriment to the parts.

The other situations at which the artery may be compressed are the upper part of the thigh, just below Poupart's ligament, and those portions of the limb where the vessel may be pressed against the shaft of the femur, by directing the instrument outwards and backwards. When the compression is designed to be permanent, as in the treatment of popliteal aneurism, it should be frequently varied, making it now at this point, and then at that, as it may be painful or otherwise; and it is, moreover, of great importance, under these circumstances, that the instrument with which it is applied should not completely encircle the extremity, lest it impede the return of the blood in the veins, and thus occasion swelling and other mischief.

The principal agent in carrying on the collateral circulation after ligature of the femoral artery is the profunda, the branches of which soon become greatly enlarged, and by their anastomoses with the articular offsets of the popliteal artery, send the requisite supply of blood to the distal portion of the limb.

LIGATION OF THE DEEP FEMORAL.

The deep femoral artery has been known to be the seat of spontaneous aneurism, but the occurrence is extremely rare, and very difficult of diagnosis. The profound situation of the tumor, underneath the muscles at the anterior and inner part of the thigh, will usually serve to throw some light upon its character; but the only reliable sign is the continuance of pulsation, thrill, and bellows sound, and somewhat of an augmented intensity in the swelling when firm pressure is made upon the superficial femoral, about two inches below Poupart's ligament, so as to direct the blood with increased force into the deep vessel. The proper remedy, in such a case, as well as in traumatic aneurism, would be ligation either of the affected artery, or of the common femoral, an inch below its origin, where it may be felt beating immediately beneath the skin and aponeurosis. The application of the ligature to this vessel is sometimes required on account of hemorrhage.

The deep femoral is usually given off by the common femoral, from an inch and a half to two inches below Poupart's ligament; sometimes, however, it is detached considerably higher up, and occasionally it is furnished by the external iliac or by the femoral, immediately after the commencement of this vessel. The artery, soon after its origin, passes inwards, behind the superficial trunk, and gradually places itself under cover of the long adductor muscle, between which and the great adductor it afterwards descends towards the femur, near which it pierces the latter muscle, and finally disappears on the posterior part of the thigh. When this vessel is injured, the wound will, of course, serve as the readiest guide to it; and two ligatures will always be necessary to put an effectual stop

to the hemorrhage. In case of aneurism, the artery may easily be exposed, near its origin, by an incision similar to that made in ligating the common femoral, or the superficial femoral, in the superior portion of its extent, beginning an inch below Poupart's ligament, and descending obliquely in the direction of the inner border of the sartorius muscle. The deep trunk may then be readily traced to the requisite extent, and should be encircled a few lines below the origin of its two circumflex branches.

LIGATION OF THE POPLITEAL.

The popliteal artery, situated deeply in the cavity of the ham, in close relation with numerous important structures, is very difficult of access, especially in fat subjects. Fortunately it is seldom necessary to attempt its deligation, as wounds and traumatic aneurism here are of extremely infrequent occurrence. The artery is in intimate connection by its outer and posterior surface with the popliteal vein, from which it is not always easily detached. Sometimes the vein is double, and then the artery lies between the two trunks, closely and firmly embraced by them. The popliteal nerve is separated from the vessels by a thick layer of fat; superiorly it lies exterior to the artery, but as it descends towards the leg it gradually winds around it to place itself along its internal border.

There are two points at which the popliteal artery may be exposed for the application of the ligature; these are its superior third and its inferior third. The middle portion of the vessel is never interfered with, on account of its great depth, its near proximity to the knee-joint, the unyielding character of its lateral boundaries, and its intimate connection with the accompanying vein and nerve.

The artery may be ligated in the upper third of its extent, where it is more accessible than anywhere else, by carrying a vertical incision along the outer border of the semimembranous muscle, for about three inches, extending down as far as the popliteal nerve. The muscle is then drawn inwards and the nerve outwards, when, by the cautious use of the forceps and handle of the knife, the vein and artery will be easily found, and must be gently and carefully separated from each other, the needle being passed from without inwards.

Fig. 359.

Ligation of the Popliteal at its upper and lower parts. *a.* The Popliteal Vein. *b.* The Popliteal Artery. *c.* The Posterior Saphenous Vein The Popliteal Nerve, on the outside of the Artery, has been omitted in the Diagram.

Exposure of the artery, in the lower third of its extent, may be effected by a vertical incision between the heads of the gastrocnemial muscle. Care is taken not to injure the posterior saphenous vein and nerve, which lie close by, but to draw them, along with the popliteal nerve, away from the knife. The artery will be found to be deeply imbedded in the ham, partially concealed by the popliteal vein, but projecting somewhat to its outer side.

In his attempts to expose the popliteal artery, the surgeon must be careful not to make too free use of the knife, for fear of wounding the articular branches which are given off at a right angle, and which might, if injured, cause embarrassing hemorrhage.

This artery sometimes requires to be ligated on account of the subcutaneous rupture of its coats, as in a case reported by Mr. Poland. No difficulty was experienced in effecting the object, although much blood had been effused. The patient did well until the third day, when gangrene came on, followed by amputation and death. The ends of the artery, separated by an interval of an inch and a half in length, were each included in a ligature. In two other cases in which a double ligature was applied to this vessel, the result was also unfavorable.

LIGATION OF THE ANTERIOR TIBIAL.

The anterior tibial artery may require to be tied on account of hemorrhage or traumatic aneurism, and the best plan always is to take the external wound as a guide to the seat of the injury. The vessel, whose course is indicated by a line drawn from the head of the fibula to the base of the great toe, may be secured at three different points.

The artery, in the superior third of its extent, lies underneath and between the anterior tibial and common extensor muscles, and may be exposed by a vertical incision, four inches in length, carried down in the direction of the line just mentioned. The skin and

superficial fascia being divided, the aponeurosis is split open upon a director to the full extent of the outer wound; the two muscles are then separated from each other along their raphé, and the artery, which lies in close contact with the interosseous ligament, is surrounded with the ligature in such a manner as not to injure the accompanying veins. The anterior tibial nerve is exterior to the vessels.

In the middle third of the leg, the relations of the vessel are essentially the same as in the upper, except that the long extensor of the toe is interposed between the anterior tibial

Ligation of the Anterior Tibial at various parts. The Wounds are supposed to be held asunder. The Ligature is under the Vessel.

and common extensor. The artery is still deep-seated, and a long incision is required for its full exposure. A branch of the peroneal nerve sometimes attaches itself to the artery here, and must be drawn away before passing the ligature.

In the inferior third of the limb, the artery lies on the tibia, between the tendons of the common extensor of the foot and the proper extensor of the great toe, the latter overlapping it on the inside. The vessel here is, therefore, comparatively easy of access.

The *dorsal artery* of the foot, the continuation of the anterior tibial, is easily tied in any portion of its extent, as it runs down across the instep, its course being indicated by a line extending from the centre of the ankle-joint to the posterior extremity of the first interosseous space. It lies under cover of the integument and aponeurosis, and may readily be exposed by carrying the knife along the outer border of the tendon of the long extensor muscle of the great toe. The incision need not exceed one inch. The vessel is accompanied by a nerve and two veins.

LIGATION OF THE POSTERIOR TIBIAL.

The posterior tibial artery occasionally requires ligation on account of wounds and aneurisms of its own caliber, and, if the operation is performed high up, the task is one of the most arduous and perplexing that a surgeon can be called upon to execute. It has fallen to my lot to tie it in this situation in three instances, and the difficulties in two were very great, having been increased tenfold by the confused condition of the parts, in consequence of the large quantity of extravasated blood. In one of the cases the artery had been laid open by a pistol ball, and in the other by a dirk-knife: the hemorrhage was profuse, and could only be effectually controlled by the ligature. The third case was one of aneurism in the lower part of the vessel.

The situation of this artery is very deep; its course, at first obliquely inwards, and then vertical, is indicated by a line extending from the centre of the ham to the fossa between the heel-bone and the inner ankle. It is covered in the superior two-thirds of its extent by the gastrocnemial, soleal, and plantar muscles, but during the remaining portion it lies immediately below the integument, except at its commencement, where it is slightly overlapped by the tendo Achillis. It is accompanied and embraced by two veins, one being on each side of it. The attendant nerve lies internal to it in the upper part of the leg, but as it descends it crosses the artery superficially, and places itself along its outer margin. The posterior tibial artery is sometimes double, and cases occur in which it is unusually small, or even absent, its place being supplied by a large peroneal artery.

The artery may be exposed and tied in the upper and middle portions of its extent in one of two ways. The first consists in detaching the gastrocnemial muscle for about four inches along the inner border of the tibia, and cutting across the inner head of the soleal, by reflecting which we come directly down to the posterior layer of the aponeurosis of the leg, the free division of which brings the vessel at once fully into view. Care must be taken to avoid the internal saphenous vein, which runs close along the line of incision. The limb, during the operation, should rest upon its outer side, the leg being flexed at the knee, and the foot extended.

In the other method, originally suggested by Mr. Guthrie, the artery is laid bare by a long, vertical cut, extending through the centre of the muscles of the calf. Its advantages are, first, that the artery, being more directly approached, is more effectually under our control, and, secondly, that there is less danger of bagging, if blood and pus are poured out. The length of the incision need not exceed that in the other operation, and the hemorrhage is generally insignificant.

Fig. 361.

Of these two methods, I give a decided preference to that of Mr. Guthrie, who has justly stigmatized the other "as difficult, tedious, bloody, and dangerous." That it is so is fully confirmed by my own observation, in a case of circumscribed, traumatic aneurism of the lower portion of the tibial artery, in a man, between thirty-five and forty years of age, a patient at the College Clinic. Although I made a very long incision, and was ably assisted in the operation by Professor Wallace and others, such was the difficulty experienced in separating the artery from the concomitant veins, that, despite the utmost caution, one of the latter was wounded, followed by such an annoying hemorrhage that I was finally compelled to include the artery and the wounded vessel in the same ligature. The case went on well for a few days, when pyemia ensued, rapidly terminating in death.

In a case of pistol-shot wound of the posterior tibial artery, in a man, thirty-six years of age, I experienced no difficulty in finding and securing the vessel by what may be called the "direct method," so forcibly advocated by Mr. Guthrie. The incision required to expose the artery is, it is true, a long and deep one; but it has the advantage, and a very great one unquestionably it is, of affording more room, and of admitting of more thorough drainage.

Ligation of the Posterior Tibial, at various parts. The Wounds are held asunder, and the Ligature is under the Vessel.

The posterior tibial sometimes requires ligation in the lower portion of its extent, between the heel and ankle. Taking the pulsation for his guide, the surgeon makes an incision, about two inches in length, directly along its track, which is nearly midway between the two points here indicated. The direction of the incision should be somewhat curvilinear, with the concavity towards the inner malleolus. The artery here lies beneath three aponeurotic layers, which must be successively divided upon the director, when the needle is passed under the vessel from behind forwards, care being taken not to include the accompanying veins and nerve.

In consequence of the superficial situation of this artery in the lower portion of its extent, a convenient point is afforded between the inner malleolus and the tendo Achillis for the application of pressure in the treatment of hemorrhage of the sole of the foot. The effect may be greatly increased if the circulation is also arrested in the anterior tibial, as may readily be done by placing a compress over it, just above the joint. A bandage is then extended from the toes upwards as far as the ankle, around which it is to be passed in the form of the figure 8, until the bleeding is completely arrested. Sometimes a metallic arch may advantageously be stretched across the front of the joint, one end resting upon each compress, the object being to ward off injurious pressure.

Wounds of the arteries of the foot are often followed by troublesome hemorrhage, which may, eventually, lead to great, if not fatal, exhaustion. The cause of this is twofold, the deep situation of the plantar arteries, and their extensive and intricate anastomoses with each other. The general arrangement bears a very strong resemblance to that of the palmar arteries. It might be supposed, at first sight, that, when these vessels are wounded, the bleeding could readily be arrested by regular, steady, and systematic compression. This, however, is not the case. Why, then, not ligate them at once, without waiting until the patient is blanched and worn out by the loss of blood, in the vain hope that the operation may at length put a stop to it? That this is the proper course is unquestionable; hence the sooner it is carried into effect the better. The only objection to it is the large wound that is obliged to be made in order to expose the bleeding vessel; but this

must be done at all hazard, and a ligature applied to each extremity, lest the hemorrhage should continue through the recurrent circulation.

It has been proposed in these cases to cut down upon and tie the principal arteries of the leg, and we read of instances in which even the great trunk of the thigh was ligated for such a purpose. Such a procedure cannot be too strongly condemned, as being contrary both to common sense, anatomical knowledge, and sound experience. The experiment of tying both the tibial arteries has been tried again and again under such circumstances, and the almost invariable effect has been complete failure; as might, indeed, have been anticipated from a careful study of the disposition of the vessels of the foot.

Notwithstanding the somewhat pointed manner in which I have here spoken against compression in hemorrhage of the plantar arteries, it is but proper to add that I have seen this very method occasionally put a most prompt and effectual stop to the flow of blood. I recollect distinctly the case of a little girl, which came under my observation many years ago, where I succeeded, by a single dressing, in arresting an exhausting and daily recurring hemorrhage of upwards of a month's duration. A graduated compress placed over the orifice of the bleeding vessel, and confined by a roller extending from the toes upwards, aided by elevation of the leg and cold applications, constituted, as it always should when such a procedure is adopted, the means employed on the occasion.

Sometimes we may advantageously resort to the expedient of compressing the anterior and posterior tibial arteries by means of two corks, placed directly over these vessels, opposite the malleoli, and bound down firmly by a suitable bandage, passed around the foot and leg in the form of a figure 8. The corks should each be wrapped up in a bit of patent lint, and should be at least three-quarters of an inch in length, and of proportionate thickness and breadth, otherwise it will be difficult to make them retain their proper position. When the compression is obliged to be made with great firmness, it may be well, in order to defend the soft parts, to extend a piece of sheet lead across the limb under the bandage.

When the parts are so much inflamed and swollen as to render it difficult, if not impossible, to expose the affected vessel, the hemorrhage may sometimes be promptly arrested by acupressure, or by percutaneous ligation.

Venous hemorrhage, of an obstinate character, sometimes occurs in the foot, either as the result of accident, of amputation, or of the excision of a morbid growth, as a fibrous, fatty, or malignant tumor. The immediate cause of the trouble is generally a varicose and enlarged condition of the veins, the blood welling up from the bottom of the wound from numerous points. A tampon of cotton wet with a strong solution of subsulphate of iron, thrust firmly in contact with the bleeding vessels, covered with dry lint, usually arrests the flow in an instant; when this fails, the edges of the wound should be transfixed with a pin, and then drawn tightly together with a thread, as in the operation for harelip. In a case of Chopart's amputation of the foot, followed by profuse venous hemorrhage, in which all the more ordinary remedies had been fruitlessly tried, Dr. Beck, of Freiburg, promptly succeeded by ligating the posterior tibial artery three inches above the internal ankle. The veins were very numerous and extremely enlarged.

LIGATION OF THE PERONEAL.

The peroneal artery, after running a short distance, passes obliquely downwards and outwards to reach the fibula, along which it descends until it arrives near the outer malleolus, where it divides into its two terminal branches. It may be secured, in the upper portion of its extent, by making an incision, long and vertical, towards the fibular side of the leg, through the bellies of the gastrocnemial and soleal muscles; and inferiorly, as it lies between the outer malleolus and the tendo Achillis, by a cut at least two inches and a half in length, directed upwards and outwards towards the fibula. The vessel here rests upon the interosseous ligament, close to the inside of the bone, under cover of the long flexor of the great toe, which must be detached as far as it may be necessary from the bone, and drawn downwards.

CHAPTER VI.

INJURIES AND DISEASES OF THE VEINS.

The affections of the veins requiring to be noticed under this head are, wounds, hemorrhage, inflammation, varicosity, the formation of phlebolites, and the introduction of air.

SECT. I.—WOUNDS AND HEMORRHAGE.

Of wounds of the veins not much need here be said, as they rarely exhibit any difficulty in regard to their treatment, or much danger in respect to their termination. Like wounds of the arteries, they may be produced by various weapons, and are, therefore, distinguished by different names, as incised, punctured, lacerated, contused, and gunshot. They are always followed by more or less hemorrhage, according to the size of their caliber, the blood issuing from them in a continuous stream, of a dark, purple color. When the division is complete, there is hardly any retraction, or annular constriction, and hence the bleeding often progresses until it proves fatal, especially if the vessel is large and superficial, as in wounds of the jugular and femoral, fainting not materially favoring the formation of a clot. Partial wounds, of whatever direction, will also bleed copiously, if they are at all extensive, and no mechanical obstacle is offered to the flow of blood. If the incision is small, exhibiting the character of a puncture rather than of a cut, the bleeding, after having continued for some time, will gradually cease, in consequence of the formation of a minute, but gradually increasing, clot upon the edges of the wound. These phenomena may often be witnessed in ordinary venesection at the bend of the arm, the clot adverted to constituting one of the impediments to the flow of the blood, and occasionally compelling the operator to open another vein. In gunshot wounds, severing a large vein, the hemorrhage frequently proves as suddenly fatal, or nearly so, as in corresponding lesions of an artery; or, life being preserved by the narrow state of the wound, or the valve-like disposition of its walls, the blood may be extensively, and, perhaps, most prejudicially, infiltrated into the intermuscular and subcutaneous connective tissue.

The best examples of lacerated wounds of the veins are met with in those frightful accidents in which a limb is torn either partially or completely from the body. In such condition the hemorrhage is generally extremely small, perhaps hardly amounting to a few ounces; a circumstance due partly to paralysis of the vessels, and partly to the shreddy state of their tunics, together with the shock experienced by the system, the whole tending to the rapid coagulation of the blood, and the prevention of its further escape. This disposition is shared alike by the veins and arteries.

Spontaneous rupture of a vein sometimes occurs, as for example, of the external saphenous, from excessive distension of its weakened and attenuated coats, so frequent in varicose enlargement of this vessel. A similar accident may befall an internal vein. Contused and lacerated wounds of these vessels may be caused in various ways, one of the most common of which is the passage of a heavy vehicle over the body, or body and limbs. A case of rupture of the ascending cava, thus occasioned, has been reported by Piper. The vein was torn longitudinally near the auricle by the passage of the wheel of a gun-carriage over the chest.

Copious venous hemorrhage occasionally occurs after excision of different kinds of morbid growths, especially when they are seated upon the back or the side of the chest, parts in which the veins are either destitute of valves, or very imperfectly supplied with these important structures. I lately removed a sarcomatous tumor, the size of a double fist, from the inferior region of the scapula, in a man, thirty-eight years of age, in which I had an excellent illustration of this occurrence. Thirty hours after the operation, copious hemorrhage set in, the loss of blood amounting to at least a quart and a pint. Upon removing the stitches, and sponging away the clots, the most careful search failed to detect any bleeding vessel, or even the slightest oozing anywhere, thus conclusively showing, the more especially as there was no further trouble after-

wards, that the blood must have proceeded from valveless veins. Similar occurrences are occasionally witnessed in the stump, after amputation of the larger limbs, the blood issuing directly from the open mouths of the larger veins, in consequence of the deprivation of their valves from the manner in which the vessels are divided in the operation.

The chief danger from wounds of the veins arises from loss of blood, and inflammation of their tunics. The latter occurrence is occasionally observed as a consequence of the operation of bleeding at the arm with a foul or blunt lancet. Ordinarily, however, there is little risk of this kind, the parts readily uniting by adhesive action, since there is no impediment to this process from the sanguineous current, as there is, under similar circumstances, in an artery; all is calm and quiet within, and the most extensive wounds are often repaired in an almost incredibly short time.

The *treatment* of a wounded vein is generally very simple, merely by compress and bandage, and attention to position. If seated superficially, the mere contact of the edges of the breach generally promptly arrests the hemorrhage, without any direct application to the vein itself. In the operation of bleeding, the only dressing commonly employed, after the necessary quantity of blood has been evacuated, is a small pledget of muslin, placed immediately over the part, and confined by means of a roller. The slight inflammation that follows furnishes the requisite amount of plasma, and in less than twenty-four hours the union is generally so firm as to render it difficult to break it. When the divided vessel is deep-seated, as in wounds of the neck, axilla, groin, and thigh, and the bleeding cannot be arrested by compression, the only resource is the ligature, or, this failing, acupressure, applied in the same manner as in a bleeding artery.

A great dread of the ligature, as a hemostatic agent, in venous hemorrhage, until lately existed among surgeons. Convinced that this apprehension had been much exaggerated, Dr. S. W. Gross has examined the subject statistically, in an elaborate paper published in the American Journal of the Medical Sciences for January and April, 1867. Most of the cases tabulated by him refer to the internal jugular vein, wounded either accidentally, or in the removal of morbid growths. Of 43 cases, in which this vessel was tied, only 4 terminated fatally from the effects of the operation, the cause in all being secondary hemorrhage. In only one instance was there any evidence of pyemia; in none of diffused phlebitis. The average period at which the ligature separated was 13 days, the minimum 4, and the maximum 23. In the femoral vein, the detachment occurred, on an average, on the 11th day, in the axillary on the 9th, and in the external jugular on the 7th.

It will thus be seen that the danger of ligating veins is in great degree, if not entirely, unfounded. I have myself repeatedly tied the larger vessels of this kind, both in amputations and in the removal of tumors, with entire impunity, and the operation has often been practised, with equally happy results, by other surgeons. One important circumstance, upon which it is impossible to place too much stress, has been developed in the paper above alluded to, that the ligature should always be applied in such a manner as to effect complete occlusion of the vein. If any portion of its cavity be left open, there will be great danger of secondary hemorrhage, if not also of the entrance of air, pyemia, and diffused inflammation, owing to the insufficiency of the clots, and of the adhesions of the sides of the vessel.

The practice of applying a lateral ligature, as it is termed, when a vein is merely nicked, pierced, or partially divided, should be discarded, as the operation is almost invariably followed, on the detachment of the thread, by fatal hemorrhage, as will be perceived by a reference to the tabulated cases of Dr. S. W. Gross. In wounds of the internal jugular vein, fatal reflux bleeding will be likely to arise unless the vessel is tied at both ends.

Styptics are not suitable for the arrest of hemorrhage from a vein, unless the mouth of the vessel is previously occluded by a compress. Even the most innocuous article of this class, the subsulphate of iron, is dangerous, from the fact that it gives rise to the formation of large and numerous clots which afterwards become a source of irritation, liable to be followed by pyemia and diffusive erysipelas.

Tying the main artery of a limb for the arrest of venous hemorrhage has been practised successfully, in one instance, by Professor Langenbeck. The occasion for the operation was the removal of a large fibrous tumor of the thigh, in which the femoral vein was accidentally divided at Poupart's ligament. The bleeding was excessive, but ceased instantly upon ligating the already exposed femoral artery. The patient did well. A similar result, as is proved by cases quoted by Dr. Crisp, follows in

wounds of a vein made accidentally during the operation for popliteal aneurism. Langenbeck recommends ligation of the main artery of a limb whenever it is found that compression is of no avail in hemorrhage from large venous trunks. He thinks the simultaneous ligation of the principal vein improper, from its tendency to cause thrombus. Such practice should, in my opinion, be avoided; first, because to cut off the supply of blood suddenly from an extremity is attended with great risk of mortification; and, secondly, because I have never seen an instance in which venous hemorrhage could not be readily arrested by the compress or ligature. Acupressure has not been sufficiently tried as a means of checking venous hemorrhage. I have employed it in numerous cases with satisfactory results.

Rest is of great moment after wounds of the veins; it should be absolute, for the slightest motion may break up the adhesions, and endanger the part by inflammation. Exclusion of the air is also very desirable, and may be secured by compress and bandage alone, or by these means, aided by collodion.

SECT. II.—DISEASES OF THE VEINS.

Inflammation of the veins, technically called phlebitis, is occasionally an idiopathic affection; most commonly, however, it arises from injury inflicted either directly upon those vessels, or indirectly through other structures. It frequently follows upon severe accidents and surgical operations, and, when this is the case, it is apt to give rise to pyemia, or multiple abscess, a disease which, as stated elsewhere, nearly always proves fatal. Phlebitis is a much more common affection than arteritis, and differs from this lesion still further in its liability to terminate in suppuration, which arteritis seldom does, the ordinary product of the latter being plastic matter, not pus. Another peculiarity of phlebitis is its tendency to extend along the vessels towards the heart, thus greatly increasing its dangers. Recent researches, however, render it probable that this tendency is much less frequent than was formerly imagined. The affection is sometimes confined to one vein; but, in general, it involves a considerable number, either simultaneously or successively. In the former case it is said to be circumscribed; in the latter, diffused. Finally, it may be acute or chronic.

1. *Acute Phlebitis.*—The symptoms of acute phlebitis are not always well marked. When the affected vessels are superficial, their course is generally indicated by the existence of a corresponding number of red lines, which, on applying the finger, feel like hard, rigid cords, exquisitely sensitive to the touch, and reaching from the seat of the injury up the limb as far as the eye can follow them. The discoloration, which varies from a faint, rosy tint to deep red, or even purple, according to the intensity of the morbid action, gradually diffuses itself over the surrounding surface, and eventually exhibits all the characters which distinguish that of erysipelas. Considerable swelling usually attends, not unfrequently putting on pressure. The pain is of a sharp, smarting, or burning nature, and is generally so severe as to deprive the patient effectually of appetite and sleep.

Fig. 362.

Phlebitis; a Section of the Femoral Vein, occupied principally by Fibrinous Clots.

The constitution always deeply sympathizes in phlebitis, even when of comparatively limited extent. The disease is often, if not generally, ushered in by chilly sensations, if not actual rigors, alternating with flushes of heat; the pulse is frequent, quick, and irritable; the skin hot and dry; the stomach nauseated and otherwise disordered; the bowels costive; the urine scanty and high colored. If the patient was in ill health immediately prior to the attack, the symptoms will usually be of an adynamic character from the beginning; or, if not, they will soon become so. Excessive prostration, delirium, an icterode state of the countenance, gastric irritability, and great restlessness, are commonly prominent symptoms in every severe case of phlebitis.

The anatomical characters of acute phlebitis are swelling, opacity, and pulpiness of the internal membrane of the veins, with uniform redness, varying from light pink to deep florid. The middle and outer coats soon become profoundly injected, and their proper substance, although at first preternaturally soft and humid, is at length rendered so dense and firm that the vein feels like a hard, contracted cord. The cavity of the inflamed vessel is filled with clotted blood, as seen in fig. 362,

sometimes blended with pus or lymph, and in many cases it is lined by a false membrane, susceptible, under certain circumstances, of organization. Instances occur in which the pus is infiltrated into the substance of the vein, or collected into small abscesses beneath the serous lining. The pus of phlebitis is generally an imperfectly elaborated fluid, containing a large quantity of plastic matter, and comparatively few characteristic globules.

Acute phlebitis occasionally, but very rarely, passes into *ulceration*. The morbid action may either begin in the coats of the vessels, or it may be propogated to them during the progress of disease in the neighboring structures. Thus, in scarlatina, after the more immediate effects of the malady have disappeared, abscesses are liable to form in the neck and fauces, which have been known to communicate with the internal jugular vein, ending in copious, if not fatal, hemorrhage. The subjects of such occurrences are, for the most part, young children of a weak, cachectic constitution, and the danger is generally in proportion to their exhausted condition at the time of the accident.

Acute phlebitis is always a dangerous, and often a fatal, disease, few persons recovering when the morbid action is well established or extensively diffused. This remark is true both of the traumatic and idiopathic forms of the disease; also of external and internal phlebitis, or of inflammation of the superficial and deep-seated veins. The pus formed in the affected vessels, commingling with the blood, soon poisons the system, and thus renders the heart, brain, and spinal column unfit for the performance of their functions.

The *treatment* of phlebitis cannot be conducted with too much caution. When the disease is situated superficially, an attempt should be made, by leeches, blisters, iodine, and nitrate of silver, to circumscribe the morbid action, and thus prevent the formation of pus. Such a result, however, is not to be expected when the disease involves the internal or deeper veins, where the inflammation often makes great, if not irreparable, progress before the surgeon is aware of its true character, and where, consequently, treatment of every kind is of little or no avail. All lowering measures are generally inadmissible, even when the patient is comparatively young and plethoric; debility, great and marked, is sure to arise, and to call imperatively for the use of tonics and stimulants. Purgatives are exhibited to clear out the bowels and correct the secretions; and mercury is given in frequent and liberal doses with a view to early and decisive constitutional impression, the best form being calomel, or calomel and blue mass. The addition of morphia will be required for the threefold purpose of preventing undue purgation, allaying pain, and inducing sleep. The best stimulants are milk punch, quinine, and iron, especially the tincture of the chloride.

If abscesses form their contents must be evacuated by early and free incisions; the internal organs must be diligently watched, and any complications that may arise must be met by appropriate measures. The hemorrhage that follows ulceration must be arrested by compression and styptics.

2. *Chronic Affections.*—The characters of chronic inflammation of the veins differ considerably from those of the acute form. The coats of the vessels are usually so much thickened, hypertrophied, and indurated, as to preserve, when cut across, their cylindrical figure, like an artery. The redness is of a brownish tint, interspersed with numerous shades of gray, violet, or purple; and the inner membrane, rough and shrivelled, may easily be raised in large, opaque shreds. In some instances, the vein is dilated, or contracted, obstructed with clotted blood, lined by lymph, or filled with pus.

The disease sometimes passes into *ulceration*, but the occurrence is much less frequent than in the arteries. Commencing most commonly at one or more points of the inner membrane, it gradually extends to the other tunics, which it sometimes completely erodes. The immediate effect of this accident is an effusion of blood, which may be so great as to produce fatal results. The ulcers, which affect various forms, are occasionally quite numerous, and spread over a large extent of surface.

The veins are sometimes laid open during the progress of malignant disease, the ulceration extending from the exterior towards the interior. The hemorrhage caused in this way, especially when it proceeds from the larger veins, as the jugular or femoral, may be so great as to occasion death in a few minutes.

Chronic phlebitis is observed chiefly in the veins of the inferior extremity, and in those of the spermatic cord and of the ano-rectal region, as a complication of hemorrhoids. The principal symptoms are pains, of a sharp, pricking, or dull aching character, tenderness on pressure, and a sense of fulness or distension at the seat of the disease. The treatment is gently antiphlogistic, removal of the exciting cause constituting an object of primary importance.

There are certain states of the system in which the veins attain a very great size, and,

consequently, carry an inordinate amount of blood. This *hypertrophy*, for so it may be termed, is very conspicuous in chronic affections of the joints, and in various kinds of tumors, both vascular and malignant. It is always conjoined with hypertrophy of the arteries, and forms one of the most serious obstacles to the cure of certain diseases.

Obliteration of the veins is by no means uncommon, and is nearly always the result of inflammation. Sometimes it is caused by the pressure of a tumor forcing the sides of the vessel closely in contact, and so converting it into a dense, fibrous cord. The largest veins are sometimes thus obliterated. Such a condition is extremely liable to be followed by dropsical effusions and other ill effects inimical to health and life.

Loose concretions, *phlebolites*, or vein-stones, varying in size from a currant to a pea, are occasionally found in the interior of these tubes. Commonly of a yellowish, brownish, or bluish color, they are of a hard, brittle consistence, and of an oblong, oval, or spherical form, with a smooth, even surface. When divided, they are found to be made up of several thin but distinct lamellæ, disposed concentrically around a small delicate nucleus, frequently consisting of fibrin. The number of these concretions is extremely variable; occasionally as many as ten, twenty, or even thirty, are observed. They are generally met with in the smaller veins; more frequently, perhaps, in the spermatic, uterine, vaginal, vesical, hemorrhoidal, and splenic, than in any other. In the saphenous and its branches they often exist in connection with varicose enlargement. Their composition is principally phosphate and carbonate of lime, with a small amount of animal matter, probably albumen, and a trace of oxide of iron.

SECT. III.—VARIX.

A varicose and dilated state of the veins is by no means uncommon, especially in the lower classes of working people, and in mechanics whose avocation compels them to maintain habitually the erect posture. The veins which are most liable to suffer, in this respect, are those of the inferior extremity and of the spermatic cord, but those of the abdomen, scrotum, vulva, trunk, and face are also occasionally implicated, while those of the superior extremity are almost exempt from the disease. Nevertheless, an example of great enlargement occasionally occurs in them, as in a case recently under my observation in a man sixty-one years of age, in which the affection was complicated with varix of the corresponding shoulder and side of the chest. Of the deep-seated veins, those most frequently affected are the jugular, azygos, subclavian, and hemorrhoidal. I have met with a number of cases where there was apparently a varicose diathesis, almost all the principal veins in the body being abnormally tortuous and dilated.

Age exerts a remarkable predisposition to this disease. Thus, varicose enlargement of the spermatic veins is most common in young men soon after the period of puberty; while, in the inferior extremity, the greater number of cases occur after the thirtieth year. In the hemorrhoidal veins, the malady is most frequent in elderly subjects.

The veins, in this disease, are preternaturally large, tortuous, knotty, and convoluted, or as if they were folded upon themselves, being augmented both in diameter and length, and observing a singularly serpentine course, as they proceed to their place of destination. Their coats are hard, dense, and elastic, rolling under the finger like fine cords, with, here and there, a portion that retains its normal characters, or that is uncommonly thin and expanded, as if it were ready to give way under the slightest exertion. In cases of long standing, they frequently offer a good deal of resistance to the knife, perhaps even emitting a sort of grating noise. On being laid open, they are found to be rough and irregularly sacculated, strong bands being sometimes stretched across their interior, which divide the tube into small cells, occupied by coagulated blood, phlebolites, or fibrinous concretions, in a state of organization. In the advanced stages of the disease many of the valves are broken down, if not completely destroyed, while in recent cases they are simply thickened, indurated, displaced, or ruptured. These changes, which are generally most conspicuous in the internal saphenous vein and its branches, are obviously brought about by chronic inflammation, or by repeated attacks of the acute form of that disease, and often lead to great and irreparable mischief. Occasionally, the affected vessels are converted into dense, rigid, and impervious cords, altogether disqualified for the discharge of their functions. In confirmed cases of varix of the lower extremity, the superficial, intermuscular, and deep-seated veins most commonly suffer together. Very frequently, indeed, the disease begins in the latter vessels, and gradually, through the intermuscular branches, extends to the former.

The state of the vessels here described is well depicted in fig. 363, taken from a patient of mine, a stout, robust, laboring man, upwards of fifty years of age. The enlargement, which was much greater than any of the kind I had ever seen, was principally situated on the inner surface of the limb, and was associated with similar disease of the veins of the scrotum, penis, and abdomen.

The disease may be caused in various ways. In the inferior extremities of pregnant females, it is generally induced by the pressure of the distended uterus, creating a mechanical impediment to the return of the blood in the iliac veins, and, indirectly, in the saphenous. Wearing tight garters, drawers, or stockings, may also occasion the disease, and a similar effect is brought about by the habitual maintenance of the erect posture. Hence the disease is very common in persons who are compelled to stand much. Varix of the hemorrhoidal veins generally depends upon habitual distension of the rectum and frequent straining in defecation. The causes of varicocele are still imperfectly understood, although there is reason to believe that the disease is most commonly developed under the influence of onanism, and other mechanical obstruction tending to weaken the spermatic veins.
Fig. 363.

Varix of the Leg.

A natural predisposition to varicose enlargement occasionally exists in certain individuals; the veins seem to be unusually large and feeble, and become tortuous and dilated under the most trifling obstacles to the onward movement of their contents. When this is the case, the disease often occurs simultaneously in different parts of the body, superficial as well as deep.

The effects of varicose veins vary according to the situation of the malady. In the legs, the pressure of the enlarged and distended vessels is always productive of a good deal of pain, of a pricking or stinging nature, of tumefaction of the skin and connective tissue, and of more or less tenderness along the track of the affected veins. In the more aggravated cases, ulceration of the integument is apt to take place, commencing usually at one particular spot on the inner surface of the limb, and gradually progressing until a large sore is established, called, from this circumstance, the varicose ulcer, which always heals with difficulty, and which occasionally extends into the enlarged veins, causing copious, if not fatal, hemorrhage. In the spermatic veins, the disease may give rise to atrophy of the testicle, and to distressing neuralgic pains; while in the hemorrhoidal it leads to the formation of piles, and other disagreeable effects.

Although the development of varix is generally slow, cases occasionally occur in which the reverse is the case. During the latter months of utero-gestation, the veins of the feet, legs, and thighs often attain an enormous bulk in a few weeks, and I have seen repeated instances of a similar kind in the spermatic and hemorrhoidal veins. In the inferior extremity, the disease, after having gone on for some time, often remains stationary for an indefinite period, neither perceptibly advancing nor receding. In some instances it undergoes a sort of spontaneous cure, inflammation being set up in the affected veins, followed by the formation of fibrinous concretions, by which their caliber is ultimately rendered so completely impervious as to compel the blood to seek other channels. Instead of this favorable result, the inflammation occasionally leads to erysipelas, abscess, pyemia, and even death. Varicocele never proves fatal, nor does varix of the hemorrhoidal veins, although both are, at times, a source of severe suffering.

Treatment.—The treatment of varix resolves itself into palliative and radical. The former consists, as the term implies, in the removal of the exciting cause of the disease, and the adoption of such remedies as tend to relieve the part and system of suffering without positively curing the malady. In varicocele, onanism must be interdicted; in varix of the hemorrhoidal veins, straining and constipation must be counteracted; and in varicose enlargement of the veins of the lower extremity, all sources of constriction must be removed, together with whatever else may have a tendency to weaken, irritate,

and inflame the diseased structures, and thereby occasion further enlargement. Giving artificial support to the affected veins often has a good effect. Hence the use of the suspensory bag in varicocele, and of the laced-stocking in varix of the saphenous vein. In every form of the lesion, great benefit accrues from attention to the general health, and from the occasional administration of an active purgative, which, by clearing out the bowels, thus affords a freer passage to the blood in the diseased veins towards the heart. If the patient is very plethoric, blood may sometimes advantageously be abstracted. In varix of the legs commonly nothing affords more prompt and satisfactory relief than a good bleeding at the arm; and the same remedy must be called into requisition, along with astringent and anodyne lotions and perfect rest of the parts, when the veins are unusually tender and painful from accidental access of inflammation.

For the radical cure of this disease numerous operations have been devised, a few only of the more important of which need to be noticed here, as the rest have either fallen into merited neglect, or are too dangerous to justify their repetition. Besides, the claims of these different operations will more naturally come to be considered in speaking of the several varieties of varix, as varicocele and hemorrhoids. There are really only two operations which, according to my experience, should ever be practised for the permanent relief of this disease, namely, the ligature and the caustic issue; and if we apply these remedies to individual forms of the lesion, it will be found that the former is exclusively adapted to varicocele and hemorrhoids, and the latter to varix of the feet, legs, and thighs. Both procedures are extremely simple, but, although this is true, they should never be employed without a thorough preparation of the part and system; and I deem this the more necessary, because, in the great majority of cases upon which we are obliged to operate, the disease is rather an inconvenience than a serious evil, threatening loss of limb and life. I will not pretend to assert that there are no cases of varix when an operation is not absolutely necessary; to do this would be absurd; what I mean is simply that no man, however skilful or experienced, should endanger his patient's life by rushing headlong into measures which, if injudiciously used, may lead to the worst results. The preliminary treatment should be mild, but of longer duration than in ordinary diseases; the object is to remove all irritation that may exist in the affected veins, to soothe and calm them, in order that they may be the better prepared to withstand the rude assault about to be made upon them. To accomplish this object, the patient must be subjected to light diet, gentle purgation, and almost absolute rest in the recumbent or semierect posture, for at least a week. This will be the more important if he be plethoric, intemperate, or very excitable. When it is remembered how intolerant the veins are of injury and of surgical interference, such precautions cannot be considered as idle.

The operation with the ligature is either direct, as in piles, or subcutaneous, as in varicocele, and in either case it is as safe as it is effectual. The principle on which it operates is that of strangulation, by which the enlarged vessels are converted into a slough, which is subsequently detached by ulcerative action. For this purpose it is necessary to draw the cord with great firmness, so as to produce this result in the shortest possible period, as well as with the least suffering. When the ligation is direct, as in hemorrhoids, it is always necessary to encircle the base of the tumor, or to tie it as near as practicable to its point of attachment to the bowel. When the base is unusually large, it is sometimes transfixed with a needle armed with a double ligature, one of which is then drawn around each half of the morbid growth, the object being its more effectual strangulation. The subcutaneous operation is particularly applicable to varicocele, although it is sometimes also practised upon the leg and thigh in varix. It is performed by means of a stout spear-pointed needle and a strong ligature, introduced in such a manner as to avoid the spermatic cord, the instrument making only two punctures, one in front of the scrotum and the other behind, by retracing its steps after it has effected transfixion. The ends of the cord are then firmly tied in the usual manner, the pressure being increased from day to day until the ligature is completely detached, or but feebly adherent.

In operating upon the veins of the inferior extremities, my experience is that the safest plan is the establishment of a series of issues, made with the Vienna paste, the proper mode of applying which will claim special attention in the section on varix in the second volume.

The after-treatment is not to be disregarded in these operations. The great danger is a bad form of erysipelas, connected, doubtless, with phlebitis, its tendency being to diffuse itself extensively over the system, and to give rise to pyemia and typhoid symptoms. I have not myself, however, witnessed any such effects in any of my cases, and I am inclined to ascribe my good fortune more to the pains I have always taken in preparing my patients

than to any particular skill in performing the operation or in conducting the after-treat-ment. If everything goes on well, little else will be necessary than strict attention to the diet, and quietude of the part and system, with an occasional laxative ; if erysipelas super-vene, the use of opium, quinine, and iron will be indicated, along with milk punch, and the application of iodine, astringents, and emollient cataplasms.

Excellent cures of enlarged veins have been effected by injections of the solution of subsulphate of iron, consisting of one part of the officinal preparation to twenty or thirty parts of water. Used stronger than this, the remedy is liable to excite undue inflammation.

SECT. IV.—INTRODUCTION OF AIR.

A fatal, although, fortunately, not a common occurrence, incident to certain operations, is the accidental introduction of air into the veins. It is most frequent in operations about the neck, face, and axilla, and was first noticed, as a distinct event, in 1818, by Beau-chesne, in exsecting a tumor from the cervical region of a young man, in which it was necessary to disarticulate and raise the clavicle. At the moment of effecting this, the patient became faint, and, exclaiming that he was dying, expired in less than half an hour afterwards. The examination of the body revealed the existence of an aperture in the internal jugular vein, at its junction with the subclavian, through which the air, causing the fatal result, had, doubtless, entered the circulation. Shortly after this, a similar acci-dent happened to Dr. Mott and Dr. Stevens, as well as to several European surgeons, so that, in due time, the attention of the profession became fully aroused to the nature and importance of the subject.

The disastrous effects of the introduction of air into the venous circulation were known, long ago, to Wepfer, Vander-Heyden, and other physiologists ; but they were lost sight of, in great measure, until attention was recalled to the subject by the experiments of Bichat, Nysten, and Magendie, who showed that a very small quantity of this fluid, sud-denly injected into the jugular vein of dogs and other animals, was sufficient, in most cases, to cause death almost instantaneously. On the other hand, it has been found that a large quantity, as, for example, several cubic inches, will not destroy life, if it be intro-duced slowly, the air, in this case, combining with the blood in such a manner as to pre-vent it from producing any serious mechanical inconvenience. Upon dissection, air is readily discovered in the cavities of the heart, as well as in other parts of the circulatory apparatus, thus accounting satisfactorily for the fatal event.

The *symptoms* which characterize the entrance of air into the venous system are essen-tially those of cerebral apoplexy. The patient is generally seized, suddenly and unex-pectedly, in the midst of the operation, with a sense of faintness, or a horrible feeling of terror, oppression, and exhaustion, inducing him to believe, and, perhaps, to exclaim, that he is dying. The countenance, in a moment, assumes a dark, livid hue, the body is agi-tated with convulsive movements, the breathing is slow, difficult, and stertorous, the muscles are completely relaxed, the pulse is feeble and almost imperceptible, the pupils are dilated, and the individual is wholly unconscious. In short, he dies in a state of pro-found coma, like a person in a fit of apoplexy. On applying the ear to the cardiac region, the action of the heart is found to be excessively oppressed, the organ struggling power-fully to overcome the mechanical obstruction caused by the admixture of the gaseous and sanguineous fluids, which, swept slowly and heavily along over the fleshy and tendinous columns, occasions a loud, churning noise, synchronous with the contraction of the left ventricle, and at the same time a peculiar thrill, or vibratory sensation, perceptible by the hand as it rests upon the chest.

Such are the effects usually observed when air has been introduced suddenly, even in small quantity, into the venous circulation ; and there is a strong probability that they will steadily increase in severity until they prove fatal, despite the most judicious and energetic measures that may be employed to counteract them. The period at which death occurs varies from a few minutes to several hours ; occasionally life is destroyed almost with the rapidity of lightning, and in most cases in from twenty to forty-five or fifty minutes. The fatal event, if not instantaneous, is always preceded by a rapid reduction of the temperature, and by a diffusion of the lividity over the whole body, the surface being of a leaden hue, as in death from asphyxia. Cases have been noticed in which, after the symptoms had continued for some time in a very bad form, the purplish appearance of the cheeks was suddenly replaced by a reddish tinge, affording evidence, although gen-erally of a deceptive character, of speedy reanimation and ultimate recovery.

The immediate cause of death, in this accident, has been variously explained ; indeed,

it is remarkable what little coincidence of opinion there is upon the subject among writers. From the fact that air has occasionally been found in the right cavities of the heart, after surgical operations in man, and in animals after experiments, it has been assumed that it was the inability of this organ to contract upon its contents, and thus send a sufficient quantity of blood to the lungs and brain for the due performance of their functions. Others have maintained that the primary trouble is in the pulmonary tissues. Thus, Mr. Erichsen supposes that it depends upon the manner in which the air and blood are beaten up together in the right cavities of the heart into a spumous fluid, which is unable to pass through the lungs, thus depriving the brain and spinal cord of their due supply of blood, and inducing fatal syncope, usually attended with convulsions. In opposition to this view, it may be stated that, if air be injected in considerable quantity into the carotid artery of an animal, all the phenomena of apoplexy, such as stertorous breathing, loss of sensibility, and spasmodic rigidity of the muscles, will instantly be produced, and soon occasion death from obstruction of the cerebral circulation. Whatever of truth these different explanations may embody, it is evident that the secondary effect of the presence of the gaseous fluid, that which really causes the fatal termination, is the want of a sufficient quantity of oxygenated blood in the great tripod of life, the heart, lungs, and brain.

If the patient survive, the transition to health is seldom instantaneous; on the contrary, several hours generally elapse before he recovers his consciousness and strength. In a case mentioned by Dr. Warren, the man, after having lain in a state of insensibility for two hours and a half, awoke as if from a profound sleep, still breathing, however, apoplectically. The night was passed without any accident, and on the following morning he was as well as usual, except that he had a headache, and some soreness in the chest. Sometimes the patient recovers from the immediate consequences of the accident, but dies afterwards from pneumonia, produced, probably, by the irritating effects which the fluid exerts upon the pulmonary capillaries, and through them upon the air-vesicles. Such an occurrence, however, is uncommon.

The local phenomena accompanying the introduction of air into the veins are of great interest, particularly in their diagnostic relations. In general, there is some noise, or sound, so loud and distinct as to be plainly perceived by the operator and his assistants, and which, occurring in combination with the sudden distress of the patient, is of the utmost value as a means of discrimination. In some cases, the sound is of a hissing nature, like that arising from air rushing into a narrow and exhausted receiver; in some, it is bubbling, clucking, or lapping; in some, gurgling, sucking, or licking. The immediate causes of these variations are, the size, shape, and situation of the opening in the injured vein, the quantity of blood in the wound, and the volume of the vessel and the relation which it bears to the surrounding parts. Whatever may be the nature of the sound, or the degree of its intensity, it cannot, when once heard, be forgotten, and is always clearly characteristic of the accident. In addition to this phenomenon, there is occasionally, but by no means constantly, an appearance of bubbles of air about the wound in the vein, especially if it be somewhat deep-seated.

The veins through which air is usually spontaneously admitted in surgical operations are those about the neck, particularly the external and internal jugular and their immediate branches. It may also enter by the veins of the face, the axilla, and the chest. Thus, in one of Dr. Mott's cases, it passed in through the facial vein during the extirpation of an enlarged parotid gland. Dr. Warren met with an instance in which it was introduced by the subscapular vein; Clemot saw it enter by the veins of the chest; and Delpech had a case in which it gained admission by the axillary vein. In operations on the trachea, and in the removal of tumors from the anterior part of the neck, the veins lying in this region might easily be wounded so as to let in air.

A case in which the introduction of a seton in the forepart of the neck was followed by the entrance of air into the veins has been recorded by Dr. Willis, of England. The patient, who had labored under chronic laryngitis, died in seven hours after the operation. The large cervical vessels were found, on the dissection, to be uninjured, but the right auricle and pulmonary artery were distended with frothy blood, and the lungs were emphysematous.

The reason why the veins in the localities here enumerated alone are subject to this accident is that they are under the influence of a suction action during inspiration, owing to a tendency to the formation of a vacuum within the chest during the expansion of the lungs. This action is naturally limited to the veins at the root of the neck, and it is here, therefore, that air is most liable to be introduced spontaneously; it may, however, as has already been stated, pass in through the veins of the face, axilla, and thorax, but in order

to do this it is necessary that these vessels should be in the condition of rigid tubes, or in a state of canalization; for if they are merely collapsed, flattened conduits, it is evident that the air will not be able to enter them, however freely they may be punctured. There are various circumstances which may induce this accidental canalization of a vein, of which the principal are the adhesion of its walls to the parts through which it passes, and the manner in which it is held during the operation, rendering it open-mouthed and gaping when divided. Sometimes the introduction takes place in a perfectly healthy vessel at a considerable distance from the root of the neck, in consequence of the tension into which it is thrown by the position of the head and arms, as happened in one of Warren's cases, where the air was admitted by the subscapular vein. The probability of this occurrence is much increased when operations are performed upon the neck, face, and axilla, for the removal of large tumors, especially such as are of a glandular nature, including veins of considerable size. In injury of the jugular veins the accident will be most likely to happen if the wound is made just above the clavicle, where the suction action is naturally strongest. Air thrown into the veins in remote parts of the body will destroy life as promptly and effectually as when it enters in the localities above alluded to, and the only reason why the accident so seldom occurs in them is that the vessels are not under the immediate influence of the respiratory organs, as they are about the neck and chest. Legallois witnessed three cases of instant death in female animals from the introduction of air into the inferior vena cava and heart by the uterine veins, and the same occurrence has been met with in the human subject.

Treatment.—The treatment of this accident is preventive and curative. For the former, different plans have been suggested, most of which may occasionally be adopted with advantage. In the first place, the operator should remember where, and under what circumstances, such an occurrence is most likely to happen; for, being thus put upon his guard, he will be more cautious in the movements of his knife, and thereby, in all probability, altogether avoid the much dreaded mischief. Secondly, when he is about to begin his incisions, an intelligent assistant should compress at the root of the neck any veins that may be within reach, and, consequently, in danger of being injured in the early stage of the procedure. As a preliminary step in operations in this region I occasionally pass a pin underneath the jugular vein, and twist the thread around it, as in the common harelip suture. In conducting the deep dissection, he should make careful use of the handle of the scalpel, as well as of his fingers, to detach the morbid structures, or to separate the sound, as the case may be, and if it be found that any veins are included within them, so as to require to be severed, they should at once be secured with the ligature at the cardiac side of the tumor. Sometimes a temporary ligature may be proper, to be removed, or tied, after the completion of the operation, according to the exigencies of the case. It has been recommended that, when we are compelled to divide any of the vessels about the neck, the patient should be desired previously to make a full inspiration; such a procedure, however, would hardly be safe unless the vessel should become instantly collapsed, and remain so afterwards. Thirdly, in operating in the different regions under consideration, care must be taken to avoid those positions of the head and arm which are calculated to produce tension and canalization of the veins. Fourthly, it having been found that the entrance of air into the veins can be prevented in the inferior animals by compressing the chest and abdomen, Mr. Erichsen strongly insists upon the propriety of swathing the body as tightly as the comfort of the patient will admit, with the view of compelling respiration solely by the diaphragm. Such a plan I should think of questionable utility, especially if the patient requires the use of an anæsthetic during the operation. Lastly, should the accident happen, notwithstanding every possible precaution, as indicated by the occurrence of the peculiar hissing, clucking, lapping, or gurgling noise, previously mentioned, or by the appearance of bubbles about the wound in the vein, compression must instantly be applied, and all further proceeding suspended until the trouble is effectually remedied.

To recover a patient from the effects of this accident, various methods of treatment have been proposed, some of which are, to say the least, anything but philosophical. Thus the idea of sucking out the air from the injured vein, a plan proposed by a French surgeon, by the introduction of a suitable instrument, such as a silver canula or catheter, amounts to little less than positive absurdity; for, independently of the difficulty and tediousness of such an operation, it would be far more likely to be followed by an additional entrance of air than the abstraction of that which has already been admitted. But, even granting, for the sake of argument, that a tube could readily be passed into the vein without the risk of letting in more air, it would not be practicable to remove the fluid from the lungs, which it must necessarily reach within a few seconds after the occurrence

of the accident. Once admitted, no skill can dislodge it, either by this or any other means. When the patient is plethoric, and has lost but little blood during the operation, it has been recommended to open the temporal artery, on the ground that it might have the effect of removing cerebral and pulmonary congestion, and thus favoring the restoration of the circulation. The utter futility of such a procedure must be apparent, when it is recollected that this congestion depends, not solely upon an imperfectly aërated blood, but also upon the presence of a spumous fluid, which the capillaries are incapable of propelling onward. The same remarks are applicable to the section of the right jugular vein, which, it has been alleged, might prove beneficial by unloading the corresponding cavities of the heart.

The fact is, all that can be done, in any case of this kind, is to make an effort to support the system. With this view, the treatment should be conducted very much upon the same principles as in syncope from the loss of blood, or in asphyxia from drowning. The patient is laid at once recumbent, with the head and shoulders even lower than the rest of the body, and, if the circulation is still going on, firm pressure is immediately applied to the axillary and femoral arteries, or the limbs are enveloped in elastic bandages, for the purpose of allowing as free an access of blood to the heart and brain as possible. Sinapisms of the most powerful kind are applied to the extremities, the spine, and the precordial region, or, what is far better, the body and extremities are thoroughly and persistently flagellated with the end of a fringed towel wet with hot water. As soon as reaction has been established, the body is wrapped up in warm blankets, at the same time that cold air is freely admitted to the nose and mouth. Brandy and ammonia are freely given, if the patient can swallow ; otherwise these fluids must be promptly injected into the rectum. Finally, as a dernier resort, artificial respiration should be established, by means of a tube introduced through the glottis, or through an opening in the larynx, and steadily and faithfully maintained until some time after all signs of breathing and circulation have disappeared.

CHAPTER VII.

AFFECTIONS OF THE CAPILLARIES.

THE capillaries are liable to enlargement, consisting of a species of hypertrophy of their tunics, with more or less dilatation of their caliber. The disease may be limited to the arterial capillaries, or to the venous capillaries, or it may involve both classes of vessels, constituting thus a kind of compound affection. However this may be, the consequence of the enlargement is the formation of a distinct tumor, which may eventually acquire a large bulk, and seriously compromise the safety of the patient, especially when it is of an arterial character. The disease is generally, if not invariably, congenital, and it is, therefore, not uncommon to find that it has made considerable progress before birth. It is to this group of lesions that the term nævus is usually applied. Vulgarly they are known as mother's marks, or blood marks. The term nævoid, or nævous-like, is also frequently employed.

SECT. I.—ARTERIAL TUMORS.

The only arterial tumor, properly so called, that can be recognized, in a practical sense, is that which was originally so ably and graphically described by John Bell, of Edinburgh, under the name of aneurism by anastomosis. His account of the disease is by far the most clear and elaborate that has yet appeared, and it is remarkable that hardly anything of importance has been added to it by subsequent observers, either as it respects its anatomy, etiology, or mode of treatment. The only error which the Scotch surgeon committed was the assertion that the lesion was peculiar to adults, and that it was a perfect aneurism.

The most common sites of the arterial tumor are the scalp, lip, nose, orbit, eyelid, cheek, and chin ; it may, however, occur in any part of the body, and I have repeatedly met with it upon the shoulder, trunk, fingers, and foot. Some years ago, I removed a considerable tumor of this kind from the big toe of a young man of twenty-two. I have also seen examples of the disease in the vulva of young girls. The texture in which it is usually situated is the connective, especially the subcutaneous and submucous ; I do not recollect ever to have seen it anywhere else, although its occasional occurrence has been

noticed in the liver, spleen, and kidney. In the bones of the skull it occupies the diploë.

The tumor is essentially composed of a network of arteries and capillaries, closely connected together by fibrous tissue, as exhibited in fig. 364. It is, in fact, originally nothing but a species of hypertrophy of the capillary vessels, commencing in a little speck, perhaps, not larger than the head of a pin, and going on gradually enlarging until, at length, it acquires an enormous volume. The arteries, which are free from the earthy and fatty degeneration, have a singularly convoluted arrangement, and, in cases of long standing, or of extraordinary bulk, some of them are often as large as a small goosequill; their walls are disproportionately thin and diaphanous, and from being pressed out laterally into short, blind pouches, it is very common for them to have a sacculated appearance. This increase in the caliber of the arteries is not limited to the tumor, but always extends some distance beyond its proper boundaries, as can readily be ascertained by a careful examination with the finger; in fact, it is sometimes easily detected with the naked eye. The general disposition of the veins is similar to that of the arteries; they are, however, usually less capacious, relatively considered, and hence the blood returns with less facility than in parts naturally constituted.
Fig. 364.

Anastomotic Aneurism.

The tissue by which the vessels are connected together is, in the first instance, nothing but ordinary connective substance, naturally existing in the part where the tumor is developed; it is perfectly soft, spongy, and extensible. In time, however, it necessarily undergoes important changes, brought about by the pressure exerted upon it by the impetuosity of the inflowing blood, and by its temporary sojourn in the midst of the morbid mass. Hence it is that, while in some situations it exists most sparingly, so much so, indeed, as to be hardly demonstrable, in others it is preternaturally abundant, and truly fibrous.

Such are the grosser elements of this form of tumor. Examined more minutely, it is found to consist of a kind of areolar structure, the cells of which, varying in size from that of the smallest pin's head to that of a pea, freely communicate with each other, not unlike those of a sponge, by means of lateral pores. These cells, which exhibit every diversity of shape, are formed apparently by the ampullar expansions of the coats of the arteries, and bear, in their general character, a considerable resemblance to those of the erectile organs, as the penis and clitoris. In old tumors of this description, some of the sacs occasionally become closed, thus assuming, as it were, an independent existence. The cause of this occurrence is probably inflammation, leading either to direct adhesion of the contiguous surfaces of the arteries, or to the formation of coagula. The contents of these cysts are either sero-sanguinolent or sanguineous. In the latter case they are generally solid.

Finally, the arterial tumor has no distinct, separate envelop; the only covering which it has is derived from the superincumbent structure, as the skin or mucous membrane, which, in time, becomes atrophied by the incessant beating of the blood beneath, and ultimately gives way by ulcerative action. In general, the surface of the tumor is of a reddish scarlet hue, with here and there a purple spot, and so transparent as to allow many of the enlarged vessels to be seen through it. Occasionally a few granules of adipose matter overlie the tumor, or are dispersed through its substance.

It will thus be perceived that this tumor is in reality not a true aneurism, preceded and accompanied by the fibrous, earthy, or atheromatous degeneration, but simply an abnormal dilatation of the capillary arteries, involving, in time, the larger arteries in their immediate vicinity, and attended by a corresponding but less developed state of the capillary and adjacent veins. It consists, in fact, clearly and distinctly, in a hypertrophied condition of these vessels; or, in other words, as was previously remarked, in a gradual evolution and growth of arteries and veins from tubules that are imperceptible by the naked eye to vessels of extraordinary size. There is no addition of new vessels, at least not originally, but the whole tumor is formed out of those which naturally exist in the part, enlarged in every direction, in length as well as in diameter, under the pressure of the steadily increasing afflux of blood. The coats of the vessel are not, it is true, as thick and firm as those of the arteries and veins, properly so called, usually are, but the aggregate capacity is so much greater than what the part naturally possesses that it must be regarded as essentially a product of supernutrition.

The origin of the arterial tumor is often ascribed to the effects of external violence, as a blow or fall, and that it may occasionally be so excited is highly probable; in general, however, it arises without any assignable cause, as a nævus, or mother's mark. Indeed,

I am inclined to think that the affection is nearly always congenital, even in those cases in which it is said to have arisen in the adult. This may be accounted for on the assumption that the nævus was originally so exceedingly minute as to have entirely escaped attention, until it began to assume an active character. However this may be, the starting-point of the disease is usually a little reddish speck, not larger than the head of a small pin, perfectly free from pain, and seated just beneath the skin, or partly in the skin and partly in the subcutaneous connective tissue. Its growth is generally very gradual, so that a number of months, and perhaps even several years, may elapse before it attains the volume of a pigeon's egg. Occasionally, however, it increases with great rapidity, and soon acquires a frightful bulk, as in a case under my care, not long ago, in a female child, thirteen months old. At birth a reddish spot, as large as a dime, was observed at the centre of the left cheek. At the end of five weeks it had nearly doubled its dimensions. A charlatan now applied some caustic substance, eventuating in a large slough. The sore, which was the seat of occasional hemorrhage, healed in a little more than two months, leaving an unseemly scar upwards of two inches in diameter, with red, spongy edges. A year after the use of the escharotic, when I first saw the child, the tumor was of immense volume, horribly disfiguring the features, and occupying the whole of the left side of the face, extending forwards to the nose and mouth, upwards to the eyelid and temple, backwards behind the ear, and downwards into the neck, its antero-posterior diameter being eight inches and a half, and the vertical six. The tumor, of a bluish color, and of a soft, spongy consistence, sensibly increased whenever the child cried, laughed, sneezed, or coughed. At its lower and back part it had a peculiar aneurismal thrill and bruit, synchronous with the action of the heart. During the last few months the inside of the cheek had become much enlarged, and now presented a knotty feel and a bluish appearance. The upper jaw, along its alveolar process, was of unusual size, evidently from the same cause, and was beginning to encroach seriously upon the mouth. The swelling was free from pain, and there was no disorder of the health.

In general, however, the tumor proceeds more slowly, and we not unfrequently meet with cases in which, after having made some progress, it remains for a while stationary. When it begins as a nævus, or mother's mark, it is not unusual for it to continue as a little reddish spot for several years, when, its activity being aroused, how or why we know not, it grows with unwonted vigor, and soon attains a large bulk. The tumor has generally an irregular outline, and rarely projects more than a third or half an inch beyond the level of the surrounding parts. It is soft and compressible, the finger sinking into it as it would into a wet sponge, but the moment the pressure is removed it regains its former volume, the blood rushing into it with a peculiar whizzing or blowing noise. Its color varies in different cases; when it occurs in the skin, or skin and connective tissue, it is generally of a reddish hue, inclined to scarlet, especially in its earlier stages; but in all cases, and especially when it lies beneath the mucous membrane, it is more commonly of a bluish or purplish color. It beats and throbs synchronously with the contraction of the left ventricle of the heart, and imparts a peculiar aneurismal thrill to the finger. Its movements are often perceptible at a considerable distance, and are always sensibly augmented under the influence of mental emotion. When of considerable volume, the tumor may produce severe pain and other inconvenience by its pressure, but, as a rule, there is little local suffering or constitutional disorder.

Such a tumor sometimes ulcerates and sloughs, causing more or less hemorrhage, and ultimately, perhaps, death, as in the case of one of my patients, a female child, ten months old, who had a large congenital arterial nævus upon the right shoulder and arm, of a dark purple color, and of a soft spongy consistence, throbbing and beating violently. Although the general health was good, ulcers, after some time, began to form on different parts of the tumor, which now became very painful and inflamed, and, in a few weeks, gangrenous. The hemorrhage which succeeds the ulceration in this affection, profuse as it sometimes is, seldom proves fatal; for, after it has continued for a while, the blood coagulates upon the eroded surface, and thus prevents further effusion. In the female, the hemorrhage is occasionally vicarious of the menstrual flux; the tumor becomes full and tense at the return of each period, and, giving way at the top, allows the blood to drain off, without serious injury to the parts or system. It has been asserted that such a growth may degenerate, changing its primitive character, and assuming one of a worse kind, as the sarcomatous. Without altogether denying the possibility of such an occurrence, I have never seen anything to justify the conclusion.

Treatment.—The treatment of this form of tumor may be conducted by excision, escharotics, strangulation, starvation, injections, and, lastly, by amputation, as when the disease occupies one of the extremities. Besides these methods, there are several others

of a more doubtful and less trustworthy character, which will be briefly noticed in their proper place.

α. *Excision* is chiefly adapted to small arterial tumors, before they have acquired much functional activity, or given rise to any enlargement of the neighboring arteries. The operation is then perfectly safe, easy of execution, and likely to be entirely successful. But if the case be neglected until the morbid growth has attained a large bulk, beating and throbbing violently at every pulsation of the heart, as if it were ready to burst, the attempt, besides proving one of immense difficulty, may be attended with so copious a hemorrhage as to cause speedy exhaustion ; we have then a formidable enemy to deal with, and we may consider ourselves fortunate if the patient do not perish from the loss of blood, gushing forth, as it will, in torrents, at every stroke of the knife. In such a case the prudent surgeon weighs well, before he begins his perilous operation, the chances of success ; he measures every inch of ground, and equips himself thoroughly, at every point, for the trials and perplexities of his portentous undertaking.

When excision is determined upon, the rule of practice is, as John Bell long ago so correctly observed, not to cut into the tumor, but around it, and yet not so widely around it as to include an unnecessary quantity of sound tissue. The operation is performed rapidly, the finger of a good assistant quickly following the knife in order to compress any important artery that may be divided, until the whole mass is completely extirpated; and it will be wise, if practicable, always to arrest the circulation in the main artery leading to the tumor before we begin the incisions. Removal being thus effected, the ligature may often be entirely dispensed with, all bleeding ceasing the moment the operation is over ; or as soon as the edges of the wound are thoroughly approximated by the twisted suture, a mode of dressing peculiarly adapted to this form of disease, on account of the hemostatic influence exerted by its compression.

Fig. 365.
Erectile Tumor. The Integument, uninvolved, has been reflected by Flaps : Transfixion is being completed, previous to Deligation. The larger Ligature, in the act of being pulled through. It fills the aperture of puncture, preventing Bleeding ; and, besides, bears a stronger strain on tying.

The cutaneous method of removing næevoid and other vascular tumors, suggested by Mr. T. P. Teale, of Leeds, has been successfully practised in a number of instances. It consists in dissecting off the skin, as a preliminary step, and then replacing it, experience having proved that, when the case is thus managed, the enlarged vessels gradually shrink, and eventually all trace of disease disappears.

β. Small arterial tumors may often be readily destroyed by *escharotics*, of which the Vienna paste, used as in making an ordinary issue, is preferable to any other. The paste is retained for fifteen minutes, being spread out sufficiently to cover the whole of the affected surface ; the application is followed up by an emollient poultice, and when the slough is detached the sore is treated upon general principles. When the tumor is very large, and so situated as not to involve any important structures, interference with which might prove prejudicial, it may be attacked, either simultaneously or successively, at several points of its extent, for the purpose of converting the whole mass into an eschar. For obvious reasons the caustic should not be used upon those parts of the body which are habitually exposed, as the face and neck.

γ. *Strangulation* may be effected by transfixing the base of the tumor with one or more pins, and then drawing a ligature firmly around them, so as to cut off at once, and effectually, its sanguineous supply. Or, instead of this, a stout, double thread may be conveyed beneath and around it by means of a spear-pointed needle, provided with an eye, one cord being tied upon one side of the swelling, and the other upon the opposite side. If the

integument be sound, the ligation is preceded by its careful division and reflection, as in fig. 365, in order that, when the morbid growth has been removed, it may be replaced, and thus serve to protect the parts from an unseemly cicatrice.

When the tumor is so flat and elongated as not to admit of inclusion by the quadruple ligature, recourse may be had to the ingenious expedient of Erichsen, which combines the great advantage of thorough strangulation with a small ultimate cicatrice, it being unnecessary to embrace an undue quantity of integument for the eradication of the disease. The operation is performed in the following manner. "A long triangular needle is threaded on the middle of a whip-cord, about three yards in length; one-half of this is stained black with ink, the other half is left uncolored. The needle is inserted through a fold of the sound skin, about a quarter of an inch from one end of the tumor, and transversely to the axis of the same. It is then carried through, until a double tail, at least six inches in length, is left hanging from the point at which it entered; it is next carried across the base of the tumor, entering and passing out beyond its lateral limits, so as to leave, as shown in fig. 366, a series of double loops about nine inches in length on each side. Every one of these loops should be made about three-quarters of an inch apart, including that space of the tumor, and the last loop should be brought out through a fold of healthy integument beyond the tumor. In this way we have a series of double loops, one white, and the other black, on each side, as in fig. 367. All the white loops should now be cut on one side, and the black loops on the other, leaving hanging ends of thread of corresponding colors."
Fig. 366.   Fig. 367.

Erichsen's Mode of Ligating Vascular Tumors.

"The tumor may now be strangulated by drawing down and knotting firmly each pair of white threads on one side, and each pair of black ones on the other. In this way the tumor is divided into segments, each of which is strangulated by a noose and a knot: by black nooses and white knots on one side, by white nooses and black knots on the other, as in fig. 367."

δ. *Starvation* may be attempted in one of two ways; either by tying the arteries which immediately feed the tumor, or else by occluding the main vessels which lead to the parts where the tumor is located. Of these two methods, preference should always, if possible, be given to the former, on account of its having a more direct and controlling influence upon the arrest of the morbid growth; when the swelling is very large, the two plans may sometimes be advantageously combined. Ligation of the arteries in the immediate vicinity of the tumor should be performed at several points at once, otherwise but little impression will be likely to follow; and care is taken, in performing the operation, not to interfere with the proper substance of the tumor, lest embarrassing hemorrhage ensue.

Deligation of the main artery leading to the parts upon which the morbid growth is situated has hitherto been practised chiefly upon the common carotid, in aneurism by anastomosis of the orbit, face, and scalp. The success has been variable, but, in the main, not very flattering, and yet I conceive that the procedure may be very proper when no other treatment is available. The misfortune, perhaps, is, that it is always employed as a dernier resort, and it is, therefore, not surprising that it should have so often failed. Dr. Mott, in one instance, tied the common carotid artery on account of a large arterial tumor, involving both orbits, the nose, and part of the forehead, in a child only three months old; the mass gradually diminished in size, and became so much consolidated as

to lead to the belief that it might afterwards be extirpated, if such a measure should be deemed expedient. The final result of the case has not been reported. In 1828, I assisted Dr. George McClellan in ligating the right common carotid for the cure of an aneurism of the corresponding side of the face and orbit, in a child five months old. The operation seemed to arrest the growth of the tumor for a fortnight, but at the end of that time its activity was again aroused, and it went on progressively increasing until it caused death by hemorrhage and constitutional irritation. Dr. Mussey, Dr. J. Mason Warren, and others, both of this country and of Europe, have tied both carotids for the cure of this disease. The first of these surgeons applied the second ligature, after an interval of twelve days, without the occurrence of any untoward symptoms. In the case of Dr. Warren, a little upwards of a month elapsed between the first and second operations; no unpleasant effects supervened, and the patient, a man aged twenty-three years, made a rapid recovery, although the arterial tumor was of enormous size, involving the mouth, face, and neck. Professor Kuhl, of Leipsic, tied the left carotid in a man of fifty-three, and, in seventy-two days afterwards, the right carotid, on account of an extensive arterial disease of the scalp. The patient recovered, but not without considerable cerebral disturbance and repeated hemorrhages from the tumor. Of 13 cases of consecutive ligation of both carotids, 2 died. Of these Ullman, Velpeau, Buck, and Foote, performed the operation on account of anastomotic aneurism of the orbit; while it was resorted to for similar disease of the scalp or face in one case by Dupuytren and Robert, by Mussey, in two instances, and in one each, respectively, by Pirogoff, Reynolds and Van Buren, Warren, Robert, Buenger, and Kuhl. In tying two such large arteries for the cure of this affection, it is important to allow a sufficient period to intervene between the two operations for the dilatation of the collateral vessels which supply the brain, so as to enable this organ to obtain the requisite supply of blood for the proper execution of its functions. Several cases, it is true, have been published, in which the ligation was performed after a very brief interval, without any serious detriment to the cerebral circulation, but this fact does not invalidate the necessity of this precaution in the class of maladies in question.

Dr. Wyeth has adduced some valuable statistics upon this subject. Of 71 cases in which the ligature was applied to the common carotid artery, 20 were cured, 20 died, 9 were improved, 16 were unsuccessful, and in 6 the result was not given. In all of these cases the operation was performed for vascular growths not implicating the orbit. Of 52 cases in which the artery was ligated for pulsating tumors of the orbit, 28 were cured, 6 died, 5 were improved, 6 were failures, and in 7 the result was not known.

ε. Of the various *injections* that have been used for the relief of this tumor, the principal are nitric acid, creasote, iodine, and perchloride of iron, introduced in small quantity, either pure or diluted, with a delicate syringe, similar to that spoken of under the head of aneurism. These fluids are all more or less irritating, while several of them are capable of exciting high inflammation; hence it is hardly necessary to add that they should be employed with the greatest possible care and gentleness. At least one case is upon record, where a drop of nitric acid, thrown into a small arterial growth of a child, caused death by convulsions. In a case under the care of the younger Teale, of Leeds, instant death followed the injection of the perchloride of iron.

The most unobjectionable injection, for the cure of this disease, is a strong solution of subsulphate of iron, a few drops of which may be deposited in different parts of the tumor, by means of a delicate syringe, the nozzle of which, introduced subcutaneously, is moved about in such a manner as to break up the coats of some of the capillary vessels. Coagulation occurs almost instantaneously, and in the course of five or ten days the whole growth drops off in the form of a slough, leaving a sore which gradually heals by granulation. By means of this salt any case of arterial or venous tumor, unless very bulky, may generally be promptly and effectually cured.

ζ. Finally, among the subordinate and less certain remedies may be mentioned the use of heated needles, vaccination, compression, the use of collodion, and the seton.

The introduction of *heated needles* into the midst of the morbid growth was strongly recommended, many years ago, by several surgeons, who followed up the suggestion by the publication of a number of cases illustrative of its efficacy. On the strength of these reports, I was induced to make trial of the remedy in a number of instances which fell into my hands shortly afterwards, but such was my disappointment that I soon abandoned it altogether as worthless.

A few cases of cure of the arterial tumor by *vaccination* have been reported, the patients having been persons whose systems had not been previously protected by this

operation. In order to prove successful, it is necessary that the virus should be inserted at different points of the affected surface, so that the resulting inflammation may be felt by the whole growth. The operation is sometimes followed by violent inflammation and high constitutional disturbance, threatening convulsions, and other serious accidents.

Compression is sometimes employed, generally by means of the pad of a truss, or of a piece of ivory, coin, or sheet lead, confined by adhesive strips, a compress, and a roller. To prove efficient, it must be made in a steady, uniform manner, the cases to which it is chiefly adapted being those in which the tumor is diminutive, and situated upon a hard, bony surface. The procedure is exceedingly unsatisfactory.

The *seton* is, perhaps, on the whole, more reliable than any other of these subordinate remedies; introduced underneath the tumor, and left there until suppuration is fully established. If the growth is small, a single thread may suffice, otherwise three or four may be necessary, or, perhaps, even a larger number. A small needle, inserted into a handle, is used, the cord being dragged through so as to fill the puncture made by the instrument, thereby preventing hemorrhage. I have treated three cases of small arterial tumors on the scalp successfully by this method.

The steady, persistent application of *collodion* has occasionally been successfully employed in arresting the growth of such a tumor, and in finally obliterating it. The treatment, which, however, is always tedious, and seldom reliable, is adapted only to the more simple forms of the disease, and to be at all effective the tumor must be situated upon a firm, bony base.

η. When the tumor is irremediable by the various measures now described, and is so situated as to admit of it, *amputation* may become necessary. Much as such a step is to be regretted, no one should hesitate to take it when the disease occupies a finger, hand, arm, foot, leg, or thigh.

SECT. II.—VENOUS TUMORS.

Under this head may be described a morbid growth composed chiefly of dilated and varicose veins, held together by connective tissue; situated, for the most part, upon the scalp, cheek, lip, and chin, but also liable to occur in other regions, as the trunk and extremities. The submucous connective substance of the mouth, tongue, and vulva may, likewise, be mentioned as occasional seats of the disease, and there is one form of hemorrhoidal tumor which evidently closely assimilates itself to it in structure. Varying in size and prominence, it may, originally, not be larger than a small pimple, which, gradually spreading in different directions, may ultimately acquire an extraordinary bulk, forming a considerable projection, and occupying a diameter many inches in extent. Its color is usually purple or claret, either continuously, or intermixed with various shades of red; occasionally it is dark-mottled, especially when the enlarged veins lie nearer the surface at one point than at another, thus rendering their contents distinctly visible through the attenuated integument. In its consistence it is soft and spongy, diminishing sensibly under pressure, but speedily regaining its former bulk when the pressure is removed. It is free from pulsation, bruit, and expansion, and is comparatively little influenced by mental emotion. Sometimes the growth is tardy, at other times rapid; it is usually congenital, but may occur at any period of life; sometimes, and most generally, without any assignable cause, and at other times as a consequence of external injury. At first there is commonly no cutaneous involvement, the tumor being strictly limited to the connective tissue; by and by, however, the skin becomes uniformly attenuated, or thickened at one spot, and atrophied at another, and thoroughly incorporated with the morbid structures. As the disease advances, but generally not until the tumor has attained considerable bulk, ulceration may take place, followed by occasional hemorrhage, chiefly of a venous character, and easily checked by pressure.

The venous tumor is usually solitary; sometimes, however, it exists in considerable numbers, either in close proximity or scattered over different parts of the body. I have frequently met with them in the same person on the scalp, face, and ears. In a remarkable instance reported by Mr. Hutchinson, of London, the child had upwards of one hundred, all of them very distinct and superficial. What is vulgarly called a mother's mark, nævus or nævoid, is by far the most common form of venous tumor.

The angiomatous growth essentially consists of a network of dilated capillaries, which are, as a rule, simply an exaggeration of those which are peculiar to the part where the morbid growth is situated. They are connected together by loose connective

tissue, are more or less tortuous in their disposition, and have exceedingly thin, delicate walls, so that, when a body of this kind is excised, they immediately collapse, the structure, which previously formed a large mass, shrinking away into a little, spongy remnant. In the specimens which I have had an opportunity of examining, no abnormal vascular cells or fibrous bands were distinguishable ; and, as the operations performed for their removal were almost bloodless, it is evident that the arteries which entered into their composition must have been few in number and exceedingly small. In very old and large growths of this kind, some of the individual veins are occasionally of enormous size, as well as remarkably tortuous, and contain fibrinous and earthy concretions, lodged in separate compartments. Such occurrences are most frequent on the trunk and buttocks.

There is a form of nævoid tumor, known as *nævoid elephantiasis*, consisting of a hypertrophied condition of the skin and subcutaneous connective substance, occupied by a dense, reticulate, spongy, venous tissue of a cavernous structure, interspersed with enlarged, varicose veins, of a truly erectile character. The skin is greatly thickened, especially at certain points of the diseased surface, rugose, fissured, or tuberculated, very hard and firm, grating under the knife, studded with long, coarse hairs, and generally a few shades darker than natural. The connective tissue is much increased in quantity, of a whitish or grayish hue, and of a dense, fibrous consistence. The affection, which is either congenital or arises soon after birth, is most common in the feet and legs ; but in a number of instances I have met with it on the face, the scalp, and the trunk, more especially the side of the chest.

The venous tumor is most easily dealt with by excision, and, unless the growth is of inordinate volume, such a procedure will be almost bloodless. If any considerable artery be embraced in the general mass, it must, of course, be secured, either during the dissection, or immediately after it has been completed. The same rule of cutting around the tumor, and not into it, should be observed here as in the removal of arterial growths.

When the knife is objectionable, a venous tumor, if small, may readily be destroyed by the subcutaneous injection of a few drops of a strong solution of subsulphate of iron. The procedure, with proper care, is perfectly safe, and productive of little suffering. I have performed the operation in several cases with very gratifying results. The diseased tissues usually slough off in from five to eight days. Electrolysis is particularly applicable to such growths, which may also be readily destroyed by strangulation, either with the écraseur, the ligature alone, or the ligature and needle, in the form of the twisted suture ; if very large, however, they must not be meddled with in this way, lest violent inflammation arising, the operation may prove fatal. In nævoid elephantiasis but little is to be done beyond the steady use of the bandage and the application of dilute tincture of iodine. If the disease be seated in the lower extremity, the employment of a laced stocking will be of service in supporting the affected structures.

Venous growths, especially when they occur as nævoids, occasionally take on malignant action, after having, perhaps, been, for many years, in great degree, if not entirely, stationary. The most common changes, under such circumstances, are the epithelial and sarcomatous. An interesting example of melanotic degeneration of a congenital nævus, in a lady, forty years of age, has been reported by Dr. Stiles.

CHAPTER VIII.

DISEASES AND INJURIES OF THE BONES AND THEIR APPENDAGES.

THE bones, being organized upon the same principles as the soft structures, are liable to similar diseases, both of a benign and malignant nature. The presence of earthy matter, however, to which they are indebted for their solidity and strength, so as to render them fit organs for locomotion and protection, exerts a modifying influence upon their diseases, not only as it respects their frequency, but also their progress, the character of their products, and the mode of their termination. This influence is particularly noticeable, on the one hand, in the difficulty with which inflamed osseous tissue suppurates, and, on the other, in the facility with which it becomes softened and deprived of its vitality, even,

apparently, under very slight action. Inflamed soft texture generally suppurates with remarkable readiness, and often becomes the seat of large abscesses; in pure osteitis, on the contrary, pus is rarely seen in any form, much less in that of abscesses, such an occurrence being usually impossible, first, on account, probably, of some peculiarity in the habits of the secernent vessels, and, secondly, because of the absence of free connective substance, which, in the soft tissues, always serves as a bed for the reception and accommodation of the purulent fluid. Bones inflame with difficulty, but when the morbid process is once fairly lighted up, it is sure to produce the most serious structural disorder, often followed by the worst consequences, as softening, protracted ulceration, hypertrophy, fragility, and even necrosis. In tertiary syphilis, gout, rheumatism, and scurvy, the bones frequently suffer immensely, receiving and harboring disease with great facility. They are a common seat of various kinds of tumors, some of which, as the exostoses, are very similar to, if not identical with, their own structure, while others are essentially different in most particulars. The carcinomatous formations have not been observed primarily in the skeleton, but the frequency of sarcoma has been a subject of remark by every systematic modern writer. Tubercle, which plays so important a part in caries of the carpal and tarsal bones, in Pott's disease of the spine, and in certain affections of the larger joints of the extremities, is very common.

SECT. I.—WOUNDS AND CONTUSIONS OF THE BONES, PERIOSTEUM, AND ENDOSTEUM.

1. *Wounds of Bones.*—Wounds of bones are liable, if at all severe, to give rise to very serious consequences, both local and constitutional. In respect to their nature they admit of the same general division as wounds of the soft parts, into incised, contused, lacerated, punctured, and gunshot. In degree they may be slight or severe; and, from their situation, they must necessarily, in all cases, be more or less complicated with injuries of other structures. The articular extremities cannot suffer without more or less involvement of the corresponding joint; and in the long bones the wound often penetrates the medullary canal, thus greatly increasing the danger to limb and life.

Among the best examples of incised wounds of the bones are the injuries inflicted in surgical operations, as in cases of excision of the jaws and joints, in chopping wood, and in encounters with the sword and sabre. Wounds made with the saw, as in the amputation of a limb, are necessarily attended with a certain degree of contusion, and are on this account more liable to be followed by severe inflammation. Punctured wounds of bone are generally caused by bullets, nails, dirks, sabres, arrows, and similar weapons, and are most frequently met with in the skull, hands, and feet. Lacerated wounds are best exemplified in fractures, especially the comminuted varieties, in which the osseous tissue is not only forcibly dissevered, but torn into numerous fragments, spicules, or splinters. Penetrating wounds are those in which the lesion extends, either partially or completely, through the substance of a bone, as, for instance, in gunshot injuries of the cranium and pelvis. Great mischief is sometimes inflicted upon the osseous tissue by mere contusion or concussion, as when a bone is struck by a glancing ball, a kick, or a fall.

1st. *Incised Wounds.*—Incised wounds, properly so called, of the osseous tissue, are uncommon. The most remarkable example of the kind that I have ever witnessed occurred in a man, thirty-nine years of age, from a cut with a butcher-knife, which completely severed the ulna at its junction with the olecranon process. The wound extended from behind forward, dividing the osseous tissue as smoothly as if it had been a perfectly soft substance, laying open the joint freely at its posterior surface, and for a time bleeding quite profusely. The treatment was conducted upon general principles, and in less than eight weeks the union was complete. The elbow, however, remained permanently ankylosed.

Incised wounds from accident occur, perhaps, more frequently in the bones of the hand and fingers than in any other pieces of the skeleton. Laborers in chopping wood often meet with such injuries, and it is not surprising, when we consider the vascularity of the parts, that they should sometimes be attended with very serious hemorrhage.

In sword and sabre wounds, portions of bone, occasionally of considerable size, are liable to be sliced off, sometimes completely, at other times partially. In the latter case, the fragment retains its attachment either by osseous tissue alone, or, as is more generally the case, by osseous tissue and soft structure.

Wounds made with the sword partake of the character of incised and contused wounds: the osseous tissue is more or less bruised by the motion of the vulnerating body, and necessarily unites more slowly than in an ordinary simple cut.

The treatment is by apposition and rest of the parts, maintained uninterruptedly until there is complete union, as there generally will be in from three to five weeks, according to the extent of the wound, the condition of the system, and the absence of complications. In incised wounds in which a portion of bone is sliced off, but still retains some of its attachments through the soft parts, the flap should immediately be replaced, and confined by sutures, plaster, and bandage. When, on the contrary, the separation is complete, reunion could hardly be expected, although the attempt might not be unworthy of trial. When a small bone, as a digital phalanx, is entirely cut through, the ends may very properly be connected with silver wire, the more especially when there is more than ordinary difficulty experienced in keeping the parts in place.

2ndly. *Contused Wounds.*—In this variety of injury, the osseous tissue is, as the name implies, not only denuded, but more or less bruised, compressed, or condensed by the forcible approximation of its component elements. The lesion is strictly analogous to a contused wound of the soft structures. The most common causes of such an occurrence are blows, falls, kicks, and gunshot violence, especially that variety of it in which the force of the bullet is in great measure spent before it reaches the bone. A bone may be severely bruised without any wound either of its own substance or even of the skin. Such an injury falls properly under the denomination of a contusion. A simple fracture, as it is called, affords a good illustration of the amount of injury which a bone may sustain without any serious participation of the soft structures.

A bruise of the osseous tissue, however slight, is always attended with rupture of the vessels of the part, and, consequently, with more or less effusion of blood, occupying its cells, and thus compressing its substance. When the infiltration is considerable, it must necessarily act as a foreign agent, exciting inflammation, which, if not kept within proper limits, may eventuate in suppuration and even gangrene. Another serious effect of such a lesion, especially if it is at all severe, is the immediate destruction of the vitality of the affected tissue, from the arrest of its circulation and innervation. The component elements are fatally compressed, being placed in a condition similar to that of a soft structure in a bruised and pulpified state. In both instances death occurs without inflammation. In general, however, this action is set up, and finally terminates either in resolution, suppuration, or gangrene. If the injury is severe, its effects will not be likely to be limited to the bone, but extend also to the periosteum, to the medullary membrane, and even to the muscles and other textures. Osteitis, periostitis, and endosteitis, indeed, are by no means uncommon after such accidents; large pieces of bone sometimes perish in this way, and the patient, after passing through intense suffering, both local and constitutional, may consider himself happy if he escapes with limb and life. The morbid action is excessive; the soft parts are enormously swollen from inflammatory deposits; the pain is agonizing; the skin exhibits an erysipelatous blush; and there is high general excitement, with a tendency to delirium and rapid prostration. Matter forms in large quantities both within the medullary canal, in the osseous tissue beneath the periosteum, and among the muscles, and, if not speedily evacuated, is apt to diffuse itself more or less extensively through the surrounding structures. Such cases are often followed by death from constitutional irritation and hectic fever. The worst attacks may end fatally in a few days. The danger is always imminent when the contusion involves the articular extremity of a large joint, as the knee, hip, or ankle.

Among the more remote secondary effects of contusion of the osseous tissue is interstitial absorption, leading to atrophy and change of form of the affected structures, as is exemplified in interstitial absorption of the head and neck of the thigh-bone after severe contusion, or contusion and concussion of the great trochanter from falls and other injuries upon the thigh and hip.

Even a very slight contusion, if a bone, as the tibia, ulna, clavicle or cranium, is only thinly covered, is sometimes followed by severe local and constitutional symptoms; the inflammation is prone to assume an erysipelatous character, and to give rise to subperiosteal abscesses, attended with great pain and swelling. In elderly subjects, contusion of the osseous tissue often gives rise to atrophy and various ossific deposits.

The diagnosis of contusion of the osseous tissue is often very difficult. Indeed, in many cases it is purely a matter of conjecture, based upon the condition of the parts, as the discolored and bruised appearance of the skin, the existence of ecchymosis, and the peculiar character of the secondary symptoms. When the bone is laid bare by the accident, the true nature of the case is often perceptible at a glance.

The prognosis should always be guarded; for, as previously stated, even an apparently insignificant injury of this kind is sometimes followed by loss of limb, if not also by loss

of life. When the lesion is very severe, the worst results may be anticipated, either proximately or remotely, the most common sources of danger being shock, erysipelas, pyemia, and hectic irritation.

In the treatment of this variety of injury, the ordinary means must be adopted for counteracting inflammation and its consequences. Leeches and saturnine lotions will be needed in the earlier stages, and afterwards free incisions to relieve pain and tension, and afford vent to the pent-up deposits. Dead bone is removed as soon as it is sufficiently detached. If symptoms indicative of the existence of abscess of the affected bone arise, recourse is had to the trephine. Amputation will be likely to be demanded when one of the principal joints has been laid open, or when, along with severe contusion, there is a comminuted fracture, serious lesion of the soft parts, or a wound of the main artery, veins, or nerves of the limb.

3rdly. *Lacerated, Punctured, and Gunshot Wounds.*—The best example of a lacerated wound of a bone is an ordinary fracture, in which the osseous fibres are forcibly torn asunder. The injury is essentially similar to a lacerated wound of the soft structures. Such a lesion may be perfectly simple as it respects the osseous tissue, or this tissue may be torn into fragments, of variable shape and size, constituting what is known as a comminuted fracture. The soft structures may be little implicated, or they may be more or less extensively bruised and lacerated, and in this way a case, in itself comparatively unimportant, may assume a most serious character, placing limb and life in jeopardy.

Punctured wounds are generally caused by bullets, and will be serious or otherwise, according to the shape and size of the projectile, the force with which it is impelled, and the importance, as a protective organ or an agent of locomotion, of the part struck. Punctured wounds of the skull, for example, however inflicted, are always fraught with danger, inasmuch as the inner table is almost invariably more or less depressed, and thus brought injuriously in contact with the brain and its envelops, leading to suppuration and other mischief. Punctured wounds of the long bones, especially such as are caused by gunshot violence, are generally attended with comminution of the osseous structure, and are to be regarded as among the most serious of accidents, liable to be followed by loss of limb and life. Even the milder forms of such lesions are often productive of the worst consequences, the primary effects being osteitis, periostitis, or medullitis, and the secondary suppuration, abscess, or necrosis.

The vulnerating body in a punctured wound either lodges in the bone, or it perforates the bone and then either makes its escape or buries itself in the soft structures. The edges of the opening of entrance in a gunshot wound are generally somewhat depressed, whereas the edges of the orifice of exit are always more or less ragged and irregular. In fact, there is the closest resemblance, in these respects, between a gunshot wound of a bone and a similar lesion of the common integument.

In regard to the treatment of these several classes of wounds, nothing need be said here, as it is discussed at sufficient length in the chapters on gunshot injuries, fractures, and other lesions.

2. *Wounds of the Periosteum.*—Simple incised wounds of this membrane are of little moment; for, if properly managed, they either unite by the first intention or they are speedily repaired by the granulating process. Suppuration and gangrene seldom occur, except in persons of dilapidated health, or when the lesion is associated with more or less contusion, or contusion and laceration. Ordinary punctured wounds also generally readily heal; gunshot wounds, on the contrary, are often followed by violent inflammation, extensive infiltration of pus, and even devitalization, not only of the membrane itself, but also of the corresponding portion of the bone and of the endosteum. A severe contusion, such, for example, as that caused by the glancing of a musket-ball, or by a blow, fall, or kick, is always a grave accident, especially if the periosteum is partially detached; for then suppuration of the membrane, if not also necrosis, will be almost sure to ensue from the disruption of the circulation and innervation of the part. Even a slight contusion of this membrane, if thinly covered, as in the tibia and ulna, may cause severe erysipelas and other troublesome inflammatory symptoms.

It is generally believed that when a bone is deprived of periosteum it must necessarily perish; but this is so only when the loss is very considerable. Ordinarily the part retains its vitality, granulations gradually spring up, and ultimately the breach is repaired by the formation of an analogous tissue, not so perfect, indeed, as the original, yet sufficiently to answer the purpose of a substitute covering. When the denudation is extensive, death is inevitable; for then the osseous tissue is deprived both of blood and nerve fluid, and, consequently, dies from the want of nourishment. The effect thus produced closely

resembles senile gangrene, the result of obstruction of the vessels by fibrinous concretions. In some cases the death of the affected bone is direct, that is, it takes place without the intervention of inflammation; in general, however, a slight action of this kind is set up, but soon terminates in gangrene, the osseous tissue being incapable of furnishing pus and of undergoing the various changes which ordinarily precede the occurrence of necrosis.

The most common cause of denudation of bone is external violence. In compound fractures attended with protrusion of the ends of the fragments, the periosteum is often extensively stripped off, and the consequence is that the part, unless speedily replaced, soon perishes. Great mischief is frequently inflicted upon this membrane by the saw in amputation. The femur, in particular, is remarkably prone to suffer from inflammation from this cause, as is proved by the immense exfoliations which sometimes occur after this operation. A bone is occasionally completely stripped of its fibrous covering by an accumulation of pus between the two opposed surfaces, in consequence of periostitis and osteitis.

Owing to the important rôle which this membrane plays in the nourishment and preservation of the osseous tissue, the utmost care should be taken to keep it intact in surgical operations, and to place it in the most favorable position for speedy reunion in cases of injury. Not a particle, unless it is absolutely dead, should be cut away. If any portion has been accidentally torn off, the denuded bone should be promptly covered with the natural tissues in its immediate vicinity, or, in the event of their loss, with an emollient poultice, to protect the exposed surface from the contact of the air, and thus afford it a chance to develop granulations. If matter form beneath the periosteum, it cannot be too speedily evacuated, on account of the danger to the corresponding bone. In the milder forms of contusions leeches and saturnine lotions are the most reliable means.

3. *Wounds of the Endosteum.*—Wounds of the endosteum, medulla, or marrow, can occur only in connection with similar lesions of the periosteum and osseous tissue, its peculiar situation precluding it from being injured by itself. The most common causes of such wounds are fractures, blows, falls, and kicks, and operations performed for the relief of disease either of the soft parts or of the bones, as amputations and resections. Among the more severe forms of wounds of the endosteum are compound, comminuted fractures from gunshot injury, laying open the medullary canal, lacerating and bruising the lining membrane, and shattering the osseous tissue into numerous fragments. Very serious injury is sometimes inflicted upon this membrane by the concussion of a bone produced by being struck by a partially spent ball, the effect being analogous to that inflicted upon the brain and its membrane when a person receives a blow upon the skull. The bone itself may in reality be very little hurt, and yet the shock transmitted across the osseous fibres be sufficient to light up violent morbid action.

The effects, immediate and remote, of wounds of the medulla, must necessarily vary with many circumstances, as the character and extent of the lesion, the presence or absence of complications, and the state of the system at the time the injury was received. Owing to the vascularity of the membrane, there is often a good deal of blood effused, the pressure of which may afterwards provoke more or less inflammation. Sometimes this is the case when the amount of fluid is extremely small, as when it presents itself simply as an ecchymosis. When the medullary canal is extensively exposed, the hemorrhage may be quite profuse, especially if the endosteum is extensively lacerated and detached. The resulting inflammation may, on the one hand, be very slight; or, on the other, so violent as to pass rapidly into suppuration and even gangrene, not only of the membrane itself, but also of the corresponding portion of the bone and of its fibrous envelop. Such cases are generally attended with severe constitutional disturbance, as well as much local suffering; the soft parts are the seat of erysipelas; and the system, especially if not in a sound condition at the time of the infliction of the injury, is very prone to be invaded by pyemia. The marrow, if exposed to the contact of the air, will be found to be, at first, of a pale violet hue from vascular congestion, and afterwards of a grayish, brownish, or ashy color, softened, diffluent, excessively fetid, and bathed with pus or sero-oleaginous fluid. The bone around is dead, the periosteum is detached, and the muscles and other tissues in the neighborhood of the disease are in a high state of inflammation.

The treatment must be conducted upon the same principles as in wounds of the bones and periosteum. The parts must, if possible, be placed in their natural relations, and every effort made to limit the morbid action. The hemorrhage may generally be checked by compression with a soft pledget of lint, sponge, or agaric, retained by the finger, until the flow ceases. All irritating applications must be avoided, as likely to excite undue

inflammation.   A free outlet should be formed for matter, and dead bone should be removed as soon as it is sufficiently detached.

SECT. II.—PERIOSTITIS.

The occurrence of periostitis is by no means infrequent, its causes being those of osteitis, with which, especially in its acute form, it is usually associated.   Among the most common of these causes are various kinds of external injury, as fractures and dislocations, blows, contusions, gunshot wounds, and the application of escharotic substances ; and the effects of gout, rheumatism, and syphilis, operating upon a disordered and dilapidated state of the system.   There is one form of whitlow which is essentially a periostitis, attacking usually one of the fingers, and liable, if neglected or improperly treated, to terminate in extensive suppuration and necrosis of the distal phalanx.   Inflammation of the periosteum, of a very severe and destructive nature, is occasionally produced by deep-seated abscesses, extending to, and irritating that membrane, as sometimes happens, for example, in phlegmonous erysipelas, where the matter burrows extensively among the surrounding tissues. Two forms of the disease are met with, the acute and chronic, the latter being the more common.

Acute Periostitis.—In the acute form of inflammation, the fibrous membrane is commonly of a reddish, pink, or lilac hue, its vessels are loaded with blood, and its substance is sensibly softened, as well as slightly thickened from interstitial deposits.   Its attachment to the bones is also considerably diminished, so that it may readily be peeled off, and the connective tissue immediately over its outer surface is generally infiltrated with sero-albuminous matter.   These changes, which are present, in greater or less degree, in all cases of periostitis, are often very conspicuous upon the fragments of a broken bone, and in incised wounds of the muscles, involving the membrane in question.

The disease not unfrequently passes into suppuration, the occurrence being particularly liable to happen in the periosteum of the bones of the inferior extremity, as the femur and tibia, and in the phalanges of the thumb and fingers ; in the former as a consequence of cold acting upon a strumous constitution, or of the effects of mercury, or of mercury and syphilis, and in the latter as a result of whitlow.

Abscesses of the periosteum are of two kinds, the circumscribed and the diffused.   Of the former familiar examples are seen in the jaws, in what is called a gum-boil, and in the ends of the fingers in whitlow.   A syphilitic node affords another illustration of such an occurrence, so frequently witnessed in the tibia, clavicle, cranium, and other superficial pieces of the skeleton.   The matter in this variety of abscess is ordinarily very thick, of a pale yellowish or yellow-greenish color, deep-seated, and of rapid formation.   The periosteum at the focus of the morbid action is spongy, swollen, congested, and infiltrated with sero-sanguinolent fluid, and the corresponding portion of the bone is in a carious or necrosed condition.

The diffused abscess of the periosteum is a most formidable disease, generally proceeding with extraordinary rapidity, and often committing the most frightful ravages in a few days.   It usually occurs in young subjects under fifteen years of age, of a scrofulous or syphilitic taint of the system.   Its most common sites are the femur and tibia, which are not unfrequently almost completely stripped of their fibrous covering.   The matter, which often forms in enormous quantities, is thin, bloody, fetid, and intermixed with flakes of lymph, clots of blood, and the débris of disintegrated tissue.   The nearest joints in these violent cases usually participate in the disease ; the synovial membrane becomes inflamed ; and, if great care be not taken, ankylosis ultimately ensues.   The bone and endosteum are always seriously involved in the mischief.

A violent form of periostitis not unfrequently supervenes upon injury of the skull, especially in punctured and contused wounds, and is very prone to terminate in extensive suppuration, the pus lifting up the pericranium from the bone, which looks white, grayish, or drab-colored, and often perishes from the effects of the disease.   In lying-in women violent periostitis sometimes occurs as a secondary affection in the iliac bone, near the hip-joint ; the suffering is excessive, and the affection is very liable to be mistaken for coxalgia, the more so, as it sometimes passes into suppuration.   Inflammation of the periosteum over the great trochanter is also apt to be confounded with coxalgia, and is often followed by abscess, caries, and even necrosis of the upper portion of the femur.

Mortification, as a termination of this disease, is uncommon.   The occurrence is characterized by a dirty, ash-colored appearance of the affected membrane, which is, at the same time, very much softened in its texture, and saturated with a foul, offensive fluid, emitting

an unmistakably gangrenous odor. Such an event is necessarily associated with necrosis of the corresponding bone, and frequently, also, with mortification of the endosteum, all perishing together in consequence of the destruction of their vascular connections. The best examples of this mode of termination occur in the periosteum of the alveolar processes of the jaws, from the abuse of mercury, and in that of the tibia, from the effects of syphilis. The sloughs, which are always tough and shreddy, are usually thrown off with considerable difficulty, owing to the tardy and imperfect action of the circumjacent structures.

The *symptoms* of periostitis are similar to those which usually attend inflammation of the deep-seated structures generally, the pain being of a violent and pulsatile character, and the swelling of the soft parts diffused and œdematous, with excessive heat of surface, and more or less constitutional disturbance. The occurrence of suppuration is announced by rigors, with a marked increase of local suffering; and as the pus accumulates, the superincumbent integument assumes a shining, glossy, erysipelatous aspect, pitting under pressure, and imparting a distinct sense of fluctuation. Both in suppuration and mortification the pain is intense, and the patient generally labors under high fever and often also under delirium. If relief be not speedily afforded, hectic irritation sets in, and death may occur from sheer exhaustion. The danger from pyemia is always great in such cases.

In periostitis consequent upon a syphilitic taint of the system, the suffering is always worst at night, the pain being of a severe, aching, or gnawing character, and invariably aggravated when the patient becomes warm in bed. Small, circumscribed swellings, or nodes, frequently exist, and are exquisitely tender on pressure and motion, the skin over them being red, inflamed, and œdematous. The contents of these swellings are generally of a thick, gummy character, possessing none of the properties of genuine pus.

In gouty and rheumatic periostitis the pain is deep-seated, wandering, or migratory, and generally very severe; the soft parts over the seat of the disease are discolored, glossy, and puffy; slight effusions of sero-plastic matter often exist beneath the affected membrane, forming small, rough, and irregular swellings, which are easily detected by the finger; the system is disordered by fever; the perspiration is acid and copious; and the urine is scanty and high-colored, depositing a large quantity of lateritious substance upon the bottom of the receiver. The most reliable symptoms, in a diagnostic point of view, are, the shifting character of the disease, the involvement of the joints, and the history of the case.

In the *treatment* of acute periostitis, a primary object is to seek for, and, if possible, to remove, the cause of the disease. The traumatic form is to be managed upon ordinary principles. Idiopathic periostitis is often a self-limited affection, tending to terminate in suppuration, despite the best directed efforts of the surgeon. Examples of this constantly occur in whitlow and in some varieties of necrosis, in which periostitis commonly plays an important part, the morbid action being apparently dependent rather upon some inscrutable constitutional trouble than any special local cause. General treatment can seldom be altogether dispensed with, while in many cases it constitutes our most valuable resource, no progress of a favorable character being made without it. In the more severe forms, bloodletting, active purgatives, and saline and antimonial preparations, will probably be required, along with anodynes, to allay the excessive pain which is so often present. The most important topical remedies are leeches, iodine, blisters, and saturnine lotions with laudanum. If great tension exist, with a tendency to suppuration, deep incisions are made without waiting for fluctuation, which is often extremely difficult of detection, unless the affected structure is very superficial, as, for example, in periostitis of the tibia. The necessity of this operation cannot be too strenuously insisted upon, as it is the only way in which we can afford prompt relief to the suffering, and obviate extensive and irremediable mischief, as must inevitably happen when the matter is permitted to burrow. After evacuation has been effected, the sides of the abscess should be brought together with a compress and bandage, otherwise copious hemorrhage may arise in consequence of the crippled and enfeebled condition of the vessels, and finally destroy the patient. When mortification takes place, the same treatment must be adopted as under ordinary circumstances.

In all the more violent forms of diffused abscess, antiphlogistics, if eligible at all, must soon give way to stimulants and tonics. The system, exhausted by the intensity of the suffering, must be supported with milk-punch, quinine, iron, and opium, in full and sustained doses. Great attention must be paid to cleanliness, the air of the apartment must frequently be renewed, and the cavity of the abscess must be injected several times a day

with weak solutions of carbolic acid, chloride of zinc, permanganate of potassium, or chlorinated sodium. During convalescence, cod-liver oil often proves serviceable.

In syphilitic periostitis the best remedy is some one of the iodides, in doses of five to ten grains three times a day, either alone or in union with bichloride of mercury. If nodes form, they will generally disappear under the influence of tincture of iodine, blisters, or mercurial inunctions, interference with the knife being seldom demanded.

Periostitis caused by rheumatism and gout requires the use of colchicum, Dover's powder, or Dover's powder and quinine, with systematic purgation, and occasionally, perhaps, slight ptyalism, with leeches, fomentations, and alkaline and anodyne liniments.

Chronic Periostitis.—The periosteum, in chronic inflammation, is thickened and indurated from the effusion of plastic matter. The hypertrophy—for so it may be termed—often involves a considerable extent of surface, forming a diffused, incompressible swelling, fibrous, cartilaginous, or even osseous in its character. Sometimes, on the other hand, the enlargement is very small and circumscribed, not exceeding, perhaps, the end of the little finger or half a dime. It may be caused by some specific constitutional poison, especially the syphilitic, or by external violence, as a blow, fall, or kick, as is often the case when it exists on the skull. However induced, its development is attended with a constant, deep-seated, gnawing pain, which is usually most severe at night when the body becomes warm in bed, and which occasionally assumes a veritable neuralgic character. After continuing for an indefinite period, the disease often remains stationary, gradually disappears, or excites suppuration in the overlying tissues.

These chronic affections of the periosteum are generally peculiarly obstinate and intractable, requiring specific remedies, frequently varied and long continued, for their cure. Iodide of potassium and mercury, Donovan's solution, and the different preparations of arsenic, with blisters, iodine, leeches, the vapor bath, and mercurial fumigations, are the means most likely to prove beneficial. In obstinate cases, resisting the ordinary remedies, free incisions, extending through the substance of the thickened and indurated membrane down to the bone, will afford more relief than anything else, especially if the wound be made to suppurate abundantly.

Bony tumors, growths, or deposits of this membrane, are to be treated upon the same principles as exostoses, properly so termed. When small, not painful, or not inconveniently situated, they will probably require no attention. Occasionally they disappear spontaneously, or under the influence of very simple remedies. Such formations are nearly always caused by the effects of the gouty, rheumatic, or syphilitic poison, and are, therefore, generally greatly benefited by iodide of potassium and a mild course of mercury.

Finally, the periosteum is sometimes the seat of the morbid growths, as the sarcomatous and fibrous, affections which will be discussed in the section on tumors of the bones.

NEURALGIA.

Neuralgia of the periosteum, as a simple, uncomplicated affection, is infrequent. The most common exciting causes are, external injury, as a bruise or contusion, miasm, sudden suppression of the cutaneous perspiration, and a syphilitic taint of the system. Any portion of the skeleton may suffer from it, but the parts most frequently assailed are the cranium, clavicle, ulna, ribs, and tibia, bones which are comparatively superficial, and which, apparently for this reason, are particularly prone to exposure and accident. I have repeatedly met with severe neuralgia in the pelvic bones, and a peculiarly obstinate form of the disease, known as coccydynia, is occasionally witnessed in the coccyx. The affection is generally associated with neuralgia of the osseous tissue, and is not confined to either sex or to any particular period of life. What influence, if any, temperament may exert upon its production is undetermined.

The characteristic symptom is violent pain, generally limited to some particular bone or portion of bone, occupying a space not larger, perhaps, than two or three inches in extent; either sharp and darting, or, as more frequently happens, dull, heavy, and aching, increased by pressure, motion, and dependency, commonly worst at night and in damp states of the atmosphere, especially when the cause is syphilitic. The pain usually remits several times in the twenty-four hours, and cases occur, as when it is of miasmatic origin, in which it is distinctly periodical, the attack occurring with the same regularity as a paroxysm of intermittent fever. However this may be, the parts are always exquisitely sensitive on pressure, with a feeling of weight and numbness; and pain, of a severe character, is not unfrequently experienced along the course of some particular nerve. There is no discoloration of the surface, or hardly ever any decided tumefaction. The general

health, at first perfectly normal, is gradually impaired, and, in the more severe cases, ultimately completely ruined.

Of the precise nature of this complaint nothing is known. It is probably, in the first instance, merely an affection of the nerves; but, as the disease progresses, other structures become involved, until, eventually, inflammatory deposits are superadded, as is shown by the thickened, spongy, and congested condition of the periosteum and the roughened appearance of the corresponding portion of the bone.

The diagnosis of this disease is not always very clear. The great trouble generally is to determine whether the morbid action is seated in the periosteum or in the bone which it covers. Practically, the distinction is of little moment, as the treatment is the same in the two complaints. The disorder, which often coexists with neuralgia in other parts of the body, is usually exceedingly obstinate and difficult to cure.

The treatment must be regulated with special reference to the nature of the exciting cause of the complaint. The most reliable internal remedies are quinine, iron, strychnia, arsenic, and aconite, either alone or variously combined, with an occasional laxative to regulate the bowels and secretions. The iodides will be required when the disease depends upon a syphilitic taint of the system. The best local applications are leeches, blisters, veratria ointment, iodine, lotions of chloroform and aconite, and hypodermic injections of morphia and atropia. In obstinate cases, attended with thickening of the periosteum, or organic disease of this membrane and the bone, nothing short of deep and extensive incision will be likely to do any good.

SECT. III.—ENDOSTEITIS, MEDULLITIS, OR OSTEOMYELITIS.

Under this name may be described a disease of the endosteum or medullary membrane, possessing all the characters of true inflammation, either acute or chronic, invariably coexisting with osteitis, and presenting itself in two distinct varieties of form, the idiopathic and the traumatic. The former, like osteitis, is most common in children and young subjects before the age of puberty, and the tibia and femur are the bones that most frequently suffer. How this variety of the disease originates is not always easy of determination. In the great majority of the cases that have come under my observation, the immediate exciting cause seems to have been cold, or sudden suppression of the cutaneous perspiration, operating upon a weak, delicate constitution. Occasionally the affection depends upon some peculiar taint of the system, as the syphilitic, strumous, or scorbutic, provoking inflammation consentaneously in the endosteum, osseous tissue, and periosteum.

The most common traumatic causes are fractures, gunshot wounds, the lodgment of foreign bodies in the substance of the bones, violent blows, contusions, concussion of the spongy tissue, and laceration of the endosteum by the saw in amputation of the limbs, of which the lesion is by no means an uncommon consequence, as is shown by the suppuration and necrosis which so often follow this operation. There can be little doubt that the disease is frequently produced by mere concussion of the limbs, transmitting its injurious effects along the canals of the long bones, thereby, perhaps, partially detaching portions of the lining membrane, and inducing serious disruption of the circulation.

The morbid anatomy of the disease is best studied in one of the long bones, as the femur or tibia, after amputation. If several days have elapsed since the operation, the membrane will be found to be of a pale pink hue, more or less injected, and apparently a little thickened; the marrow is abnormally soft; and the cells of the spongy structure of the canal are pervaded by a sero-sanguineous fluid. At a later period, when the inflammation is more fully established, the discoloration of the endosteum is of a more decided character, being of a deeper red with a shade of brown or purple, the fatty matter is broken up into a semiliquid substance, and, in addition to the bloody sanies just alluded to, traces of pus may be seen, forming numerous little points, of a yellowish aspect, which, gradually coalescing, at length assume the character of small abscesses. When the disease is uncommonly violent or protracted, portions of the endosteum are converted into veritable eschars, of a brownish color, and of a characteristically fetid color; the periosteum opposite the seat of the morbid action is detached, and the intervening part of the bone, thus deprived of its vessels, speedily perishes.

In the chronic form of the disease, which sometimes lasts for years, the osseous structure is rendered abnormally hard, dense, and heavy, the medullary canal is in great measure, if not entirely, obliterated, and the endosteum, at the seat of the morbid action, is completely destroyed. Small cavities filled with a soft, oily material, or fatty, gelati-

nous substance, and surrounded by softened, vascular, reticulated tissue, are not unfrequently found ; and cases are occasionally met with in which there are small abscesses and dead pieces of bone.   When the disease is of long standing, the affected bone is always more or less changed in its form, rough on the surface, and remarkably thickened, compact, and heavy ; in fact, greatly hypertrophied by the addition of new matter.

The *symptoms* of endosteitis are so vague and unreliable as to render it very difficult, if not impossible, to distinguish them from those which attend inflammation of the bones and their fibrous envelop.   Indeed, it is only when the disease occurs as the result of injury, as after amputation, that anything even like a plausible conjecture can be formed as to its real nature.   Under such circumstances, upon taking off the first dressings, the wound opposite the end of the bone will probably be found to be gaping and filled with pus, the bone itself being either entirely denuded, or only slightly covered with lymph below, while the medullary membrane is of a reddish or brownish color, and more or less vascular.   If six or eight days have elapsed since the operation, the exposed medullary surface will be likely to be studded with pale, flabby, unhealthy granulations, somewhat sensitive to the touch, if not decidedly painful, and discharging an abundance of thin, sero-sanguinolent fluid.   Around this red and inflamed circle, the compact layer exhibits an unusually white, glistening appearance, without any trace of reparative action ; in fact, the bone is devitalized, or, if not actually dead, soon will be.   Superadded to these phenomena, there is occasionally an escape of marrow, with or without fragments of the medullary membrane ; a sure sign of the inflamed and disorganized state of the parts.

Endosteitis is always attended with considerable swelling and puffiness of the soft structures immediately over the affected parts, but there is not necessarily any discoloration of the surface, or any unusual pain.   Considerable irritative fever is commonly present ; the skin has a peculiar sallow hue ; and there are apt to be rigors, alternating with flushes of heat, and followed by copious sweats, generally of a disagreeable acid nature.   When the disease is idiopathic, there may be tumefaction and pain, deep-seated and throbbing, at the site of inflammation, but neither of them of so distinctive a character as to be of any service in a diagnostic point of view.

However induced, or in whatever form occurring, the disease generally manifests a disposition to affect the contiguous joints, being apparently propagated from the cancellous structure to the synovial membrane.   The form in which the articular affection usually appears is that of a moderate degree of inflammation, attended with more or less effusion of synovial fluid, or of this fluid and of plastic matter, and a certain degree of pain and functional disturbance, so constantly present in disease of the joints.   When the malady is uncommonly severe, the articular structures generally suffer in a proportionate degree ; for then not only the synovial membrane, but also the end of the bone and its cartilaginous covering participate in the morbid action ; abscesses are liable to form both within and around the affected joint ; the soft structures are enormously swollen ; the skin has a glossy, erysipelatous appearance ; and there is excessive constitutional disturbance, rapidly followed by hectic fever.   If the case is not properly treated, the pus may burrow extensively among the surrounding parts, giving rise to numerous sinuses, which it will be difficult, if not impossible, to heal.   The joints that are most liable to suffer in this way are those of the knee and ankle, especially the former.

In the idiopathic form of endosteitis of young subjects the epiphyseal fibro-cartilage not unfrequently suffers, becoming inflamed, and, in the more severe cases, the seat of purulent depots.   Now and then the connection is entirely destroyed, the head and shaft of the bone being detached from each other as completely as in diastasis.

The danger in endosteitis is generally very great, as it is liable, if the disease is at all severe or wide-spread, to cause extensive necrosis, and to place limb and life in peril by the induction of inflammation in the principal veins of the corresponding extremity and the formation of abscesses in the different viscera, especially the lungs and liver.   Occasionally, it would seem to be capable of assuming a kind of endemic tendency.   Thus, in 1814, nearly all the patients at the Hotel-Dieu, in Paris, who died after amputation, and the number was very considerable, were observed to have suppuration in the medullary membrane of the long bones.

The *treatment* of endosteitis must be conducted upon general antiphlogistic principles, local and constitutional, in the hope of limiting morbid action and preventing the occurrence of suppuration and gangrene.   If the medullary canal is exposed, some mildly stimulating injection, such as a very weak solution of nitrate of silver, tannic acid, or acetate of zinc, may be useful, the part being protected from the atmosphere by lint wet with a similar fluid, or an emollient cataplasm.   When the membrane is affected in its con-

tinuity, and there is much swelling of the soft structures, free incisions may be necessary in order to relieve tension and promote the escape of the effused fluids. If there is reason to apprehend the existence of medullary abscess, as when there is deep-seated, aching, gnawing, or boring pain, with œdema of the subcutaneous connective tissue, the matter must be exposed with a small trephine, as the only chance of averting still more serious consequences.

In the strictly chronic form of the disease, our chief reliance is upon iodide of iron and iodide of potassium, with minute doses of bichloride of mercury, tonics, cod-liver oil, change of air, and counterirritation. In the more hopeless cases it may be necessary to trephine the affected bone, or even to resort to amputation.

SECT. IV.—EPIPHYSITIS.

Under this appellation may be briefly described an affection which, commencing in the osseous tissue, the periosteum, or the medullary membrane, gradually extends to, and eventually expends itself chiefly upon, the soft pulpy, vascular fibro-cartilage between the epiphysis and the shaft of a bone. This substance, which performs a most important rôle in the growth of bone, does not entirely disappear until the completion of the ossific process, about the close of the twenty-fourth year. Its main object seems to be twofold: first, to serve as a bond of connection, and, secondly, to assist in maintaining the circulation in the two pieces of bone between which it is situated.

Epiphysitis is essentially a disease of early life, the great majority of cases occurring before the tenth year. Although occasionally arising spontaneously, it is ordinarily caused either by suppression of the cutaneous perspiration or by external injury, as a sprain, blow, or contusion. Children of a strumous, scorbutic, or syphilitic taint of the system, ill-fed, pale and anemic, are its most common subjects. Sometimes it would seem to have a rheumatic origin. The attack may be primary, beginning in the epiphysary structure, but this is unusual. In the great majority of cases it is, as already stated, propagated from the neighboring tissues. However this may be, the affection is generally of an acute character, and runs its course with extraordinary rapidity and violence.

The pieces of the skeleton which are most liable to suffer are the femur, tibia, humerus, ulna, and radius, the relative frequency being in the order here stated. Of 13 cases observed by Dr. Klose, 7 affected the femur at the knee, and 4 the tibia, of which 3 involved the superior epiphysis. From the fact that so many cases of this disease were observed by one surgeon, it may be inferred that it is very frequent in Germany; in this country, on the contrary, it is very uncommon, or, if not uncommon, it has not hitherto been accurately discriminated.

The approach of the disease is generally announced by febrile disturbance, if not by a severe rigor, and by violent pain, often apparently of a rheumatic nature, in the situation of an epiphysis, in the immediate vicinity of a joint. The affected part, hot and tender, pits on pressure, but, except in rare cases, there is, as yet, no decided redness of the skin. The contiguous joint, which always participates in the morbid action even at an early period of the attack, is stiff, semiflexed, and exquisitely sensitive upon the slightest motion. In the more severe cases, there are cord-like indurations below the affected surface, evidently caused by inflamed veins and lymphatic vessels; and, if an exploring needle be introduced, it will be found that the bone is roughened and separated from the periosteum by a thin, turbid fluid. If the disease be not checked, it will gradually run into suppuration; the matter is deep-seated, and, unless promptly evacuated, will diffuse itself extensively among the surrounding structures, separating them from each other, and thus occasioning irreparable mischief. Finally, the connecting medium is completely destroyed, and the ends of the two pieces of bone may be seen and felt beneath the skin as in a common fracture. The local and constitutional symptoms are proportionately severe. The pain and swelling are excessive, the surface is covered by an erysipelatous blush, the limb is perfectly useless, and the system is exhausted by hectic irritation and profuse sweats.

The diagnosis of epiphysitis is generally very difficult. The affections with which it is most liable to be confounded are periostitis, osteitis, and endosteitis, from which it is often impossible to separate it, especially in its earlier stages. When the epiphysary fibro-cartilage has been completely destroyed, the preternatural mobility, crepitation, and displacement of the extremities of the bone will sufficiently indicate the nature of the complaint. An error of diagnosis is the less to be regretted, because the treatment of these different maladies is essentially similar.

If the patient dies in the second stage of the disease, the ends of the bones will be found to be soft and spongy, and soaked in thin, ichorous matter, the line of demarcation between them being indicated by a deep groove. The muscles are of a dark brownish color, isolated, and marked by little blackish dots of blood and pus. The veins, large as well as small, are obliterated, and occupied by hard coagula. The contiguous joint contains serum and plasma, but only in very small quantity; for, as yet, its structures are not seriously injured. When the morbid action has reached its maximum, the contents of the abscess are intermingled with clotted blood; the connecting bond at the epiphysis is completely annihilated; the shaft of the bone for a considerable distance is necrotic, denuded of periosteum, bathed in pus, and of a dark, black, or grayish color; the medullary canal everywhere exhibits traces of high inflammation, with unhealthy-looking exudation and a tendency to suppuration; and the neighboring joint, filled with pus, is extensively disorganized, the cartilaginous incrustations being broken down and the ligaments partially destroyed.

The prognosis of the disease may be gathered from its clinical history. If the milder cases occasionally get well, the more severe must, of necessity, be nearly always fatal; or, if not fatal, followed by loss of limb. The great danger is from erysipelas, pyemia, exhaustion, and hectic irritation. Recovery seldom occurs without partial ankylosis of the contiguous joint, and a slight arrest of development of the affected limb, below the epiphysis, the latter of which, as it possesses an independent vitality, continues its accustomed growth.

The treatment must be conducted upon the same principles as in periostitis, osteitis, and endosteitis; by rest and elevation of the part, anodyne and lead lotions, tincture of iodine, leeches, and, above all, early and free incisions, the knife being carried down to the surface of the bone. The system is supported with opium, iron, quinine, and milk punch. In the worst cases amputation alone holds out any hope of saving life.

SECT. V.—OSTEITIS.

Osteitis is a very common occurrence, especially in early life, owing, doubtless, to the great vascularity of the osseous tissue at that period rendering it more susceptible of disease than in old age, when many of the vessels shrink and disappear. It may be primitive or consecutive, acute or chronic; and in either event it may be limited to a particular portion of a bone, or pervade its entire length and breadth, although this is unusual. The spongy tissue suffers more frequently than the compact; and, while in the former, the disease often passes into ulceration, in the latter it more frequently causes necrosis, or mortification, the two structures being evidently endowed with different powers of resisting the effects of inflammation. The pieces most liable to be affected are those which are naturally the least covered by soft substance, as the tibia, fibula, ulna, clavicle, and frontal bone. The disease is generally slow in its progress, and a considerable period may, therefore, elapse before there is any very appreciable alteration of tissue. Cases, however, occur, in which it proceeds with immense and overwhelming rapidity, suppuration, ulceration, and even mortification appearing in less than forty-eight hours from the commencement of the attack.

If a bone affected with inflammation be carefully examined, it will be found to exhibit several important structural changes of great interest. At first it is simply enlarged, although less so than is usually imagined, because much of what appears to be an increase of volume is due rather to swelling of the periosteum than to any actual expansion of the osseous tissue itself. Gradually the affected bone loses its density, becoming softened, and infiltrated with sanguinolent fluid, of a sero-plastic nature, and assuming a bright reddish hue, the capillaries being very numerous, turgid, and distinct. As the disease advances, the osseous fibres separate from each other, and the widened intervals are immediately filled with embryonic tissue, often intermingled with little clots of pure blood. These alterations are always attended by an absorption of earthy matter, which has the effect of rendering the bone both soft and spongy, at the same time that it causes an actual diminution of its weight. The lamellæ of the compact substance are resolved, as it were, into their primitive distinctness, the Haversian canals are greatly enlarged, and the cells of the areolar texture are remarkably rarefied. When the disease has reached its maximum, the osseous tissue is frequently so soft as to be easily bent and cut. When the inflammation is superficial, affecting the outer layers of a bone, it always promptly extends to the periosteum, which, in consequence, becomes red, swollen, and infiltrated with serous and plastic matter. If, on the other hand, the inner structure is

involved, the endosteum is sure to suffer, assuming a discolored, bloodshot appearance, while the adipose matter is either rapidly absorbed, or converted into a soft, diffluent mass, of a light reddish hue, and of a peculiarly fetid character. When the inflammation of the bone is at all extensive, both periosteum and endosteum participate in the morbid action, and it is in these cases, more especially, that, the circulation being cut off by fibrinous exudation, necrosis is liable to arise.

Osteitis may terminate in resolution, the morbid phenomena gradually disappearing, and the affected structures regaining their primitive texture; or the disease may cease, and the bone become indurated and enlarged by interstitial osseous deposits; or, lastly, the inflammation may pass into suppuration, ulceration, softening, or mortification, the results resembling those of inflammation of the soft parts. It is seldom that a bone, after having

Fig. 368.
Hypertrophy of the Tibia from Inflammation.

been inflamed for any length of time, will not, upon recovery, remain somewhat hypertrophied, or larger and harder than it was before the attack, as illustrated in fig. 368. It is, in fact, nature's mode of cure, the process which she employs for repairing the mischief committed by the disease.

The causes of osteitis are either traumatic or constitutional, the former consisting of injuries inflicted in surgical operations, fractures, contusions, and wounds, especially gunshot and punctured, and the latter of a syphilitic, strumous, scorbutic, rheumatic, or gouty taint of the system, together with the operation of cold. The disease may begin directly in the osseous tissue, or this may be involved secondarily, from extension of disease from the surrounding parts. Thus, in dislocations, particularly compound, and also in simple dislocations of the larger hinge-joints, as the elbow and knee, the inflammation consequent upon the accident is nearly always communicated to the contiguous extremities of the bones, rendering them soft and brittle, and liable to give way under the slightest influences. In like manner the periosteum often becomes the propagator of the morbid action; for, although, in general, this membrane serves to ward off disease, forming a kind of wall between the soft structures and the bones, yet this barrier is not unfrequently overleaped, and inflammation kindled up in the very centre of these pieces. A great similarity is thus found to exist between the bones, periosteum, and endosteum, on the one hand, and the lungs, pleura, and bronchial mucous membrane, on the other, experience having proved that disease cannot be present in any considerable degree, or for any length of time, in any one of these component elements without being propagated to the rest, which subsequently have often to bear the chief brunt of the incited action.

Although acute osteitis is seldom dangerous, it may, nevertheless, occasionally prove fatal, especially if it be extensive, or complicated with other maladies, by the induction of erysipelas, pyemia, or constitutional irritation. Such an event will be most likely to happen in young scrofulous subjects, or in persons worn out by syphilis. The disease often terminates in serious and irremediable structural disorder of the affected part, as softening, caries, and necrosis, requiring important operations, themselves frequently a source of much risk. Recovery, under any circumstances, is generally extremely tedious.

The *symptoms* of osteitis bear a great resemblance to those of periostitis and endosteitis, and, therefore, the most adroit diagnostician often finds it difficult to discriminate correctly between them. Practically, an error of this kind is of no special moment, as the treatment is essentially similar in the three affections, but as a matter of science it is very desirable in every instance to ascertain, if possible, in what structure the disease is located, or, if all are implicated, in what degree. There is really, however, no one symptom, or group of phenomena, upon which the least reliance can be placed in this respect. It may be said that the pain in osteitis is more intense, agonizing, and deep-seated than in inflammation of the periosteum and endosteum, and yet this is so only as a general rule; in many cases the difference is too slight to be appreciable. The same is true in regard to the swelling of the soft parts, and the constitutional disorders, which are often very great

in all these affections, but, as they do not possess any distinctive features, are of no value in a diagnostic point of view.

Acute osteitis is generally attended by the same symptoms as acute inflammation of the soft structures. The pain is excruciating, the part feeling as if it were torn, or bored, or as if insects were feeding upon it; it is deep-seated, more or less circumscribed, and increased by motion, pressure, and damp states of the atmosphere; it is also usually more violent at night when the patient becomes warm in bed, especially when it recognizes a constitutional origin. The swelling is extensive, firm, and almost inelastic, pitting, perhaps, after a time, under the application of the finger; the skin has a glossy, shining appearance; and there is intense heat of the surface, conjoined, in most cases, with an erysipelatous blush. The constitution sympathizing powerfully with the local disorder, there is high fever, with excessive thirst, a full, bounding pulse, great dryness of skin, and elevated temperature, with all the minor phenomena of general incited action. If the disease is not promptly restrained, the soft parts suppurate, the event being announced by rigors and delirium, followed by copious sweats.

The symptoms of chronic osteitis are usually well marked. The bone is the seat of more or less pain, circumscribed, increased by motion and pressure, and aggravated at night, often depriving the patient of sleep and appetite. Enlargement of the affected part, with swelling and induration of the overlying tissues, is commonly a prominent phenomenon. Eventually suppuration occurs, followed by the formation of sinuses, difficult to heal, and the seat of a constant discharge of thin, ichorous, sanious, or unhealthy matter, occasionally mixed with osseous particles. The constitution frequently sympathizes with the local disorder, as indicated by the pallor of the countenance, the gradual emaciation, and other evidences of failing power.

Palpation and digital percussion have long been employed in the diagnosis of diseases of the osseous tissues, especially in the more superficial bones, as those of the head, back, pelvis, and leg. Although Roux called attention to the subject, we are mainly indebted for our present light to the researches of Professor Lücke, of Strasburg, published in 1877, and comprising a series of valuable and laborious observations upon healthy and diseased bones. Instead of employing the finger, Lücke uses a hammer, consisting of metal tipped with an acorn-shaped point of caoutchouc, and furnished with a whalebone handle, so thin as to vibrate readily under the slightest touch. The percussion should be slight or considerable according to the depth of the bone, or the amount of substance by which it is covered, and successively applied to homologous parts, in order to test their comparative sensibility, otherwise the exploration will be, in great degree, if not wholly, worthless. In examining the limbs, they should be held up and firmly supported by an assistant, to prevent the sounds from being masked by the bedclothes or other material. In inflammation of the osseous tissue, the periosteum, or endosteum, a few smart taps with the hammer are sure to elicit marked tenderness, if not actual pain, and such an exploration is especially valuable in the incipient stages of the affection before the occurrence of serious structural changes. The amount of pain elicited by the percussion will afford a tolerably correct idea as to whether the disease is superficial or deep-seated. Thus, if, on gentle percussion, the patient complain of severe aching pain, and the pain is intensified under a more decided blow, the inference is that the affection is superficial; whereas the reverse is the case if pain be experienced only under forcible percussion.

The character of the sound elicited by percussion presents important variations in health and disease. Lücke has shown that the shaft of a long bone yields a duller resonance under the hammer than its extremity, and also that the sound emitted by a bone is entirely independent of its connection with a neighboring joint, or the surrounding structures. As might naturally be supposed, all inflammatory deposits render the affected bone more or less dull on percussion; and similar effects are produced in chronic osteitis attended with enlargement and condensation of the osseous tissue, as in hypertrophy, hyperostosis, or osteosclerosis. The callus of a broken bone emits a duller sound than the bone in its immediate vicinity. In osteoporosis, in which, as the name implies, the osseous tissue is more or less expanded, a remarkably hollow sound is often produced by percussion.

Obviously such explorations are only applicable in chronic diseases of the bones, and in the earlier stages of the acute form. When acute inflammation is fully established, whether limited to the osseous tissue, or involving also the periosteum and endosteum, the morbid action affects the surrounding structures to such an extent as to render them intolerable of such rude manipulation.

Treatment.—The most important elements in the treatment of osteitis are bleeding, tartar emetic, purgatives, calomel, and opium, with perfect rest both of the part and body.

The prompt abstraction of blood by the lancet, or by leeches from the affected structures, generally proves of marked benefit in abridging suffering and limiting morbid action. Calomel is given as soon as the patient has been properly depleted, and is steadily continued until gentle ptyalism is induced. There is no remedy which exerts so powerful and controlling an influence over inflammation of bone as this; and, although it should not be used causelessly, or without due precaution, there are few cases to which it is not applicable. To prevent it from running off by the bowels, and, at the same time, to mitigate the excessive general and local distress, it should be administered in combination with large doses of opium, repeated as frequently as the exigencies of the case may seem to require.

The best local remedies, apart from leeches, are warm anodyne fomentations, light cataplasms, medicated with acetate of lead and laudanum, dilute tincture of iodine, and cantharidal collodion, the latter being applied in such a manner as to cover in the whole of the affected surface, and allowed to remain on until thorough vesication has been produced. If matter form, or even if there be merely great tension, the knife must be used, the incisions being long and deep, extending down to the very surface of the bone. Without such an expedient, relief is impossible. If the pus be allowed to accumulate, it will be sure to burrow, insinuating itself freely among the muscles, and, perhaps, even between the periosteum and bone, thereby detaching these parts from each other, and inducing extensive necrosis. What is done, in such a condition, for the soft structures, should, on the same principle, be done for the osseous. No surgeon hesitates when there is confined pus, along with great pain, tension, and swelling, to use the knife, making long and deep incisions to give vent to the effused fluid. Why should not a similar practice be adopted in suppurative osteitis? Here the matter is literally imprisoned, and can only be reached with the trephine. With a small instrument the bone is perforated at one or more points, followed by instantaneous relief, and the prevention of further inflammation, caries, and necrosis. This mode of treatment, in every respect so rational and effective, was originally brought before the notice of the profession in this country, in the latter part of the last century, by the late Professor Nathan Smith, of New Haven, and is one of the most valuable of the many practical suggestions made by that distinguished surgeon. An excellent paper, accompanied by the details of four cases illustrative of the beneficial effects of the operation, was published by his son, Dr. T. Morven Smith, in the American Journal of the Medical Sciences for 1838. In every one of these cases matter flowed freely from the bone, although only a few days had elapsed from the commencement of the attack.

In chronic osteitis the chief dependence is upon alterants, purgatives, and counter-irritation, of which the best form is an issue made with the hot iron as near as possible to the seat of the disease. A free discharge should be established and steadily maintained until the morbid action is effectually broken up. The most reliable internal remedy is iodide of potassium in union with mercury, carried, in obstinate cases, to gentle and somewhat persistent ptyalism. Such a course is particularly indicated in syphilitic osteitis, but is hardly less beneficial in the rheumatic, gouty, and strumous varieties of the malady.

Sir James Paget has described, under the term *osteitis deformans*, a remarkable variety of inflammation of the bones, characterized by enlargement and softening, with absorption of the old structure, and its replacement by fibrillar inflammatory tissue. The affection, which has also been observed by Wilks and Bryant, is usually symmetrical, and affects especially the skull and the long bones of the lower extremity, which become curved and misshapen under the superimposed weight of the body. It begins in middle age, advances slowly, does not appear to shorten life, and is attended with dull, aching pains. Three of the five recorded cases terminated in connection with carcinoma. The disease is progressive and irremediable.

SECT. VI.—SUPPURATION AND ABSCESS.

Suppuration of the external surface of bone is a very common occurrence, and may arise from various causes, as fracture and other external injury, or a syphilitic taint of the system. As the morbid action, however, which precedes and accompanies the suppuration, is usually associated with inflammation of the periosteum, it is difficult, in most cases, to determine which structure is really the source of the purulent matter. When the osteitis is of long standing, or characterized by inordinate severity, the pus is occasionally diffused through the proper substance of the bone, but such an occurrence can only happen in the event of the osseous tissue having undergone previous softening, the

removal of the earthy matter being followed by the formation of cells or cavities for the lodgment of the fluid. If a vertical section be made of a long bone, as the tibia, in an advanced state of inflammation, it will be found that the pus, presenting itself in small globules, will be scattered both through the Haversian canals and the cells of the areolar substance, no disposition being manifested in the little depots to arrange themselves into abscesses. The intermediate structure is of a reddish color, filled with fibrinous exudation, and so soft as to be easily divided with the knife. This punctiform variety of suppuration is seldom so conspicuous as in inflammation of bone complicated with endosteitis.

Abscess of bone, distinct, circumscribed, and well defined, such as is seen in phlegmonous suppuration of the soft parts, is a very uncommon affection, almost invariably a remote result of a syphilitic taint. The formation generally takes place slowly, an unusual degree of chronicity being one of its natural concomitants. The most frequent seat of the disease is the head of the tibia, as seen in fig. 369, or the head and lower extremity of that bone, the expanded and rarefied tissue of which is peculiarly well adapted to such an occurrence. The abscess ranges in size from that of a pea to that of a pigeon's egg; is generally solitary; is lined by a thin, although distinct, membrane; and is occupied by a dark-colored, ill-elaborated pus, more or less fetid, and intermingled with aplastic matter or curdy flakes similar to those observed in strumous pus. The surrounding tissues are softened, congested, and infiltrated with sero-sanguinolent fluid. The manner in which the abscess terminates is variable; when seated near the extremity of a bone, it sometimes discharges its contents into the contiguous joint; at other times, and more generally, it

Fig. 369.   Fig. 370.

Abscess in the Head of the Tibia.   Large Chronic Abscess, with a thickened, expanded Wall.

maintains its position, becoming, as it were, encysted by a deposit of new bone around it, as delineated in fig. 370. Finally, in a third class of cases, the matter continues to accumulate, apparently, for a long time, and, pressing upon the osseous tissue in every direction, gradually expands the bone into a large shell, capable of holding several ounces, and so thin and soft as to be bent and cut like cartilage.

The *symptoms* denotive of the formation of pus are usually such as characterize this event in the other tissues, only that the local suffering is generally much more intense, especially if the matter has no free vent. The existence of abscess in the interior of a bone is indicated by a dull, gnawing, heavy pain, circumscribed, deep-seated, remittent, and more like a violent toothache than anything else to which it can be compared. In many cases it is of a throbbing, boring, tearing, or lancinating nature. It is always worse at night than in the day, and is usually so intense and exhausting as to make serious inroads upon the general health, the patient soon becoming wan, sallow, and hectic. Occasionally the pain completely intermits, the parts being wholly free from suffering for many hours, and even days together; more generally, however, it is continued with partial remissions. The soft structures, at the seat of the abscess, are always exquisitely tender, especially at one particular spot directly over the matter, more or less tumefied, glazed, and œdematous, often pitting on pressure. The formation of matter is generally announced by rigors, alternating with flushes of heat; and similar attacks are very common during the progress of the disease, particularly in the early part of the night, the body being usually drenched towards morning with acid, offensive perspiration.

Although the symptoms of abscess are generally well marked, yet, as they may be simulated by other diseases, they cannot be said to be characteristic. The principal affections with which they are liable to be confounded are necrosis and deposits of new bony matter, compressing and irritating the parts so as to keep up intense pain and tenderness, similar to what is produced by collections of pus in the soft structures.

Fortunately, accuracy of diagnosis is of little consequence in these cases, as the treatment is essentially the same, whether the symptoms arise from abscess, the lodgment of dead bone, or interstitial osseous deposits. The discrimination between abscess and neuralgia, which often closely imitate each other, is of more importance, on account of the difference of treatment, but, so far as I know, there are no diagnostic signs by which the distinction can be effected.

The *treatment* of abscess of the osseous tissue is by efficient evacuation. In no other manner can the pent-up fluid be reached. The operation is not always so easy as might at first be imagined, owing to the excessive firmness of the affected bone, in consequence of interstitial deposits, which often give it the closeness and density of ivory. The best instrument is the burr of the surgical engine or a common trephine, fig. 371, from three to four lines in diameter, with sharp, well-set teeth, and fluted on the surface, so as to make a wide track. The surgeon, taking the site of pain and swelling, or the "tender spot," as his guide to the seat of the abscess, exposes the bone by a free incision, either single, T-like, curvilinear, or crucial, as may be deemed necessary, and then, turning aside a small portion of periosteum, applies the instrument. Its arrival at the abscess is generally denoted by a sudden cessation of resistance, and by the escape of a few drops of pus mingled with blood. If no matter is found after sinking the instrument to a considerable depth, it is applied at some other point, in the vicinity of the former, in the hope of a more successful result, for it is often quite impossible, in these cases, to hit the precise spot where the fluid is located in a first or even second attempt; on the other hand, however, care must be taken not to make too many perforations, lest the bone be thereby unduly weakened or suffer other injury. Moreover, it is not to be inferred by any means that although no pus has been detected, the operation will, therefore, be a failure; perhaps the instrument may have come in contact with a small sequester, lying loose in the connective tissue of the articular extremity of the bone, and by removing this rapid recovery make take place; or, instead of this, the pain and other symptoms may have been occasioned by the pressure of interstitial deposits, and the excision of a disk of bone may afford relief on the principle of taking off tension, as a free incision does in deep-seated, purulent collections in the soft structures.
Fig. 371.

Trephine.

The abscess having been opened, the cavity is washed out with a syringe, as much to get rid of the sawdust as to clear away pus and stimulate the pyogenic sac. A narrow tent is then inserted into the bottom of the opening, and the wound gently supported with adhesive strips, the after-treatment being conducted upon strictly antiphlogistic principles. The relief from the operation is often immediate, and there is no class of cases in which the efforts of the surgeon are generally rewarded with more unalloyed satisfaction. The patient, tortured for months with pain and sleepless nights, is suddenly translated from torment into Elysium.

Trephining bone for the cure of circumscribed abscess was originally performed by Petit, in the earlier part of the last century; but to Sir Benjamin Brodie, who performed his first operation in 1828, is usually ascribed the credit of generalizing it. In this country the first case of the kind is said to have occurred in the practice of Dr. Walker, of Virginia, in 1757.

SECT. VII.—EROSION.

This condition of bone is altogether different from caries, although it is often confounded with it; nor does it, in any respect, resemble necrosis. It is simply a wasting of osseous tissue, induced by the force of steady and long-continued pressure. Practically, it is of little interest, except in so far that, as experience has abundantly proved, when the exciting cause of the erosion has been removed, the affected part, unless too greatly injured, is susceptible of repair to such an extent as to enable it to perform its accustomed function as a portion of the skeleton.

Three processes seem to be necessary to the production of this lesion, softening, absorption, and pressure; the latter acting as the exciting cause. Whether the softening is of an inflammatory character, or the result merely of the disintegration of the bone-corpuscles and the deposit of sero-oleagineous fluid, is still a disputed point, and one, indeed,

which, in the existing state of the science, cannot be determined. However this may be, a certain amount of softening is an indispensable preliminary to the morbid change, as, without it, the absorbents would be unable to perform their part of the work. The most common exciting cause is aneurism; but erosion of bone may also be produced by the pressure of an ordinary tumor, or even by an accumulation of pus, as is exemplified in chronic abscess of the spine, chest, head, and pelvis. When an aneurism is brought into contact with a bone, the surface of the sac contracts firm adhesions to it; then the compact layer of the bone, becoming softened by the pressure and pulsation of the tumor, gradually disappears, and thus the morbid action progresses until, at least in the worst cases, the piece is completely perforated, as is so often witnessed in the sternum, ribs, clavicle, and bodies of the dorsal vertebræ in aneurism of the thoracic aorta. In most of such cases the sac in immediate contact with the affected bone gives way, and thus allows its contents to bathe the osseous tissue.

The eroded bone has a rough, granular surface, with various depressions and elevations, owing to the irregularity of the absorption, and, in the dried state, looks very much as if it had been gnawed by the teeth of an animal. In case the pressure is relieved, as in an aneurism cured by the ligation of its feeding artery, the bone gradually assumes a hard, dense, ivory-like consistence, the surface ultimately becomes completely smooth and polished, and the areolar texture is, in great degree, if not wholly, annihilated. As to treatment, the only thing to be done is to remove the exciting cause, and, as this is seldom practicable, the surgeon is literally powerless.

SECT. VIII.—CARIES OR ULCERATION.

Caries is a disease of the osseous tissue, strictly analogous to ulceration of the soft parts. It is essentially of an inflammatory type, and is characterized by an increase of vascularity, softening, and disintegration, the earthy matter being separated from the animal, and eliminated along with the discharges, which are often quite profuse, especially when the malady has made considerable progress. Caries differs from ordinary osteitis chiefly in this, that it is attended with actual loss of substance, the affected tissue being gradually broken down, excavated, or destroyed, whereas in the latter it retains its various elements, although in an altered condition, the principal changes consisting in congestion, softening, and the formation of granulation tissue. There are other points of difference, as the seat of the two diseases, the age at which they respectively occur, and the nature of the concomitant secretions, as will be rendered evident by a careful study of the subject.

Caries is most liable to occur in parts of the skeleton distinguished by the abundance of their areolar tissue, as the vertebræ, the skull, the sternum, the innominate bones, the bones of the carpus and the tarsus, and the articular ends of the long bones, especially of the femur, tibia, and humerus. The compact tissue is more frequently the seat of necrosis than of caries; indeed, the affection cannot occur here unless this tissue has previously undergone a certain degree of softening, so as to prepare it, as it were, for the disintegrating process which characterizes it.

Young persons are most subject to caries, particularly children under ten years of age; it is seldom that it is met with even so late as middle life, and then chiefly as a result of some specific taint of the system, more especially the syphilitic. I am not aware that sex exerts any material influence upon its production. What are called strumous children are especially obnoxious to it, and this circumstance, of which daily observation furnishes abundant evidence, long ago created a doubt in my mind whether caries is not really, in a great majority of cases, of a syphilitic nature. The more I examine the subject, the more I am satisfied of the truth of this opinion. Most of the children that come under my observation with this disease, as it occurs in the spine, the hand, foot, and ends of the long bones, present all the characteristic features of the inherited form of that affection; and I am quite sure that this experience, instead of being peculiar to myself, must be common to all intelligent practitioners.

The exciting *causes* of caries are of two kinds, local and constitutional, of which the latter are by far the more common and influential. As appertaining to the first, are various injuries, as blows, kicks, falls, fractures, contusions, and concussions, disturbing the circulation and innervation of the osseous tissue, or depriving it of its fibrous covering, and thus modifying its nutritive action. In the bones of the foot, especially those of the tarsus, the disease is sometimes induced by the penetration of a foreign body, as a nail, or splinter of wood. The sawing of the bones in amputation and resection, and their accidental division by sharp instruments, are occasionally followed by caries, both extensive and protracted.

Among the internal causes of caries may be cited whatever has a tendency to induce general debility, or to impoverish the fluids and solids, and, consequently, to exhaust the constitution. Hence we may place at the head of the list severe and protracted courses of mercury, the operation of the syphilitic poison, scurvy, scrofula, profuse losses of blood, and severe attacks of dysentery, diarrhœa, typhoid fever, and eruptive diseases, as scarlatina, measles, and smallpox. All these circumstances are capable of producing ulceration both in the skeleton and the soft parts, as is proved by the numerous sores which so

Fig. 372.

Caries of the Head of the Humerus.

Fig. 373.

Caries, with Howship's Lacunæ.

often arise in different regions of the body, as the sequelæ of these affections, and which it is usually found so difficult to cure.

A carious bone exhibits marked differences in its appearances, according to the duration of the disease and the nature of the affected piece. In the earlier stages the osseous tissue is merely inflamed, as is evinced by its vascular and softened condition; its spongy texture is rarefied, and occupied by a serous, oily fluid, intermixed with a good deal of the coloring matter of the blood, thus giving it a reddish aspect. It may be cut with the knife, or even indented with the finger, especially if the bone is a carpal or tarsal one, and, upon macerating it, the water soon becomes covered with a layer of fatty matter. Exposed to the air, it dries with difficulty, and assumes a pale yellowish hue, verging slightly upon greenish. When the disease has reached its more confirmed stages, the bone is found to be excavated, or riddled with cavities, of variable size and shape, as in fig. 372, sometimes lined by a kind of pyogenic membrane, and filled with thin, sanious, and offensive matter, without any of the characteristic properties of laudable pus. These cavities are due to the absorption of the osseous lamellæ by the granulation tissue, which has formed at the expense of the cells of the medullary spaces and the Haversian canals, and the emigrant white corpuscles, and they correspond to Howship's lacunæ, seen in minute sections, as is represented in fig. 373, from Rindfleisch. Occasionally small fragments of bone, which have been deprived of their vascular supply, lie loose in these cavities, unable to escape on account of their disproportionate dimensions. The osseous tissue is now extremely soft and brittle, breaking down readily under the finger; it is still more porous than before, and is of a grayish, brownish, or blackish color. It is apparently destitute of vessels, and yields a considerable quantity of

Fig. 374.

Caries of the Astragalus, with Softening and incipient Separation of the Cartilage.

oil on maceration. In a chemical point of view, the only notable difference between carious and healthy bone is the greater amount of cartilage and fat in the former than in the latter, the quantity of cartilage often forming as much as thirty-seven per cent., while the amount of fat is upwards of three. This quantity of fat, although much greater than normal, is not sufficient to justify the opinion expressed by some that this disease essentially consists in adipose degeneration of the osseous tissue.

The substance immediately around the softened and disintegrated structure is always more or less inflamed, red, and vascular; the periosteum is thickened, spongy,

and injected; and the endosteum exhibits all the phenomena of active participation in the disease. The compact lamella has often a worm-eaten appearance, and it is not uncommon to find it partially incrusted with bony matter. The adjacent soft parts are infiltrated with sero-plastic matter, indurated, closely matted together, and otherwise altered. In articular caries there is always more or less involvement of the cartilages, which are gradually softened and disintegrated, large pieces often coming away with the discharges, as in fig. 374.

The *symptoms* of caries are usually obscure, especially in its earlier stages, as there is no line of demarcation between it and osteitis. It is only when the affection has terminated in suppuration, ulceration of the soft parts, as in fig. 375, or the formation of sinuses, that its true character can be fully made out. Prior to this the nature of the disorder may be suspected, but cannot be certainly determined. All the symptoms, in the first instance, are those simply of osteitis. There is a dull, heavy, aching pain, which

Fig. 375.

Caries of the Tibia, with an Ulcer in the Skin.

appears to be deeply seated in the substance of the bone, and which gradually increases in extent and severity with the progress of the morbid action; the part is exquisitely tender to the touch; the skin has a glazed, reddish aspect; and there is marked tumefaction, particularly at the focus of the inflammation. The local phenomena gradually augment in intensity, the pain assumes a throbbing disposition, the swelling becomes more pointed, and presently the loose, flabby integument gives way by ulcerative action, thus allowing the contents of the abscess, for such in fact the case is, to drain off. The bone thus laid bare has a foul, eroded appearance, at the same time that it is rough and so soft as to be easily penetrated with the probe.

The sinuses leading to the seat of the disease are either straight or tortuous, and vary in length from a few lines to several inches, according to the depth of the affected bone, and, above all, the place of opening of the abscess. In general they are multiple, and have separate orifices, so as to give the cutaneous surface a sieve-like appearance. In chronic cases the sinuses are lined by a species of false membrane, and their situation is indicated by a mass of reddish granulations, somewhat mammillated in shape, in the centre of which the aperture of communication is generally easily detected with the point of the probe. This nipple-shaped body, which is often entirely insensible, and almost always bathed with pus, projects considerably above the surrounding level, and is of great diagnostic value, as it is invariably denotive of the existence of carious or necrosed bone. The sinuses do not commonly all form at once; perhaps there may be only one or two at the beginning, the rest being superadded during the progress of the disease, or, perhaps, as one closes another appears. However this may be, the parts around are always more or less indurated, inflamed, and tender on pressure.

The discharge is commonly of a thin, ichorous, sanious, or bloody character, loaded with earthy matter, more or less fetid, and so irritating as to erode the parts with which it comes in contact. It usually tarnishes silver, a circumstance which shows that it contains sulphuretted hydrogen, and is often so profuse as to cause serious exhaustion. The earthy matter, which is easily detected by its gritty character, by rubbing the fluid between the thumb and finger, frequently amounts to two per cent. of the entire discharge. Sometimes the pus is of a laudable nature, but when this is the case it may generally be assumed that it is furnished by the adjacent soft parts rather than by the bone itself. It is not uncommon for it to contain flakes of lymph, the débris of connective and aponeurotic substance, and even considerable fragments of bone and cartilage, the latter being most apt to show themselves when the sinus penetrates a neighboring joint.

There is a form of caries, which, as there is an entire absence of suppuration, may be called *dry caries:* it is most commonly met with in syphilitic disease of the cranium, and

I have also witnessed it in ulceration of the articular extremities of the long bones, especially of the head of the humerus, and of the femur. Associated with this condition of the osseous tissue, there is usually marked rarefaction of the cancellated structure with inflammatory thickening of the surrounding soft parts.

The constitutional disturbance is not always proportionate, so far as can be judged, to the amount of the local disorganization. The general health is often but little affected, especially in the early stages of the disease; by degrees, however, it begins to give way, and ultimately suffers severely. The patient loses flesh and strength, the countenance is wan and pallid, and the sleep and appetite are destroyed. If the disease is at all extensive, or if, even when it occupies but a small compass, it opens into a large joint, as, for example, the knee, hectic irritation soon sets in, and, making rapid inroads upon the system, speedily reduces the vital powers. The pain is often excruciating, particularly at night and in damp states of the atmosphere, and is one of the principal sources of exhaustion.

The *diagnosis* of caries can, in general, be determined only by a careful consideration of the history of each individual case. Until ulceration of the soft parts occurs, the nature of the disease must almost necessarily remain an enigma. The only affection with which it is liable to be confounded is necrosis, but from this it may usually be easily distinguished, before the skin has given way, by the comparatively small amount of the attendant pain, as well as by the lesser degree of constitutional disturbance, and by the fact that caries is usually met with in the short bones, while necrosis mostly occurs in the shafts of the long. When sinuses have formed, the eye, finger, and probe are usually able to determine the diagnosis, by the appearance and feel of the affected structure. In both cases the bone is roughened, but usually much more so in necrosis than in caries; in the former it always retains its original consistence, whereas in caries it is so much softened as to be readily penetrated by the probe. Nothing of a definite character can be learned from the nature of the discharge, since it is nearly identical in the two maladies. Occasionally valuable information may be obtained from a consideration of the exciting cause. Thus, osteitis from syphilis terminates more frequently in necrosis than in caries, the reverse being the case in inflammation dependent upon a scorbutic or strumous taint of the system. To this statement, however, numerous exceptions occur, and the diagnosis must, therefore, at least in most cases, be a matter of time and of repeated critical examinations.

The *prognosis* of caries is generally unfavorable, a spontaneous cure, although not impossible, being an extremely uncommon occurrence. When the disease is of limited extent, a cure may often be promptly effected by operative measures directed against the affected parts, but under opposite circumstances nothing short of resection or amputation holds out the slightest prospect of relief. In many cases the affection continues for years, apparently neither advancing nor materially receding, the general health in the mean time experiencing but little change; on the other hand, however, its progress is sometimes very rapid, and the constitutional disturbance proportionately great, hectic irritation, loss of strength, and emaciation setting in early, and steadily proceeding until the patient dies completely exhausted. Caries is less likely to terminate favorably when it assails the vertebræ and the articular ends of the long bones than when it appears in any other portions of the skeleton, except, perhaps, the carpal and tarsal bones, in which it is often so extremely obstinate as to require the removal of the limb in order to save life. The prognosis is, of course, more unfavorable in sickly and debilitated persons than in such as are healthy and robust at the time of the attack.

Treatment.—The treatment of caries should always, if possible, be conducted with strict reference to the nature of its exciting causes. When the disease has been induced by a syphilitic, strumous, or scorbutic taint of the system, remedies adapted to these respective contingencies will, of course, promptly suggest themselves, as most likely to fulfil the particular indication of the case; but where no such affection is visible, and where, in fact, nothing whatever of an appreciable character exists, the surgeon must disregard all rules, and limit himself to the application of general principles. The diet should be very plain and simple, but at the same time nutritious, so as to build up the system, and create a better state of the blood, which is generally so much at fault in caries of nearly all portions of the skeleton. Chalybeate tonics, quinine, nux vomica, and cod-liver oil are the most valuable internal remedies; aided, as occasion may seem to demand, by blue mass and alkalies, to modify and improve the secretions. Active purging is avoided, as it would inevitably prove prejudicial by its debilitating effects. Exercise in the open air is often of great service, but, to render it efficient, the diseased bone must

not be moved or irritated during its performance. Salt-bathing, followed by dry friction, will be beneficial in imparting tone and vigor to the cutaneous capillaries; and in many cases the general health is much improved by a residence at the seaside.

Irritation of the soft parts is allayed by attention to rest and position, and by the application of leeches, fomentations, and poultices, or warm water-dressings medicated with laudanum and acetate of lead. When there is much induration from deposits, the skin should be freely painted twice a day with dilute tincture of iodine, followed, if the case prove obstinate, by a large blister, experience having shown that, in superficial caries, this is more effectual in arresting inflammation than any other remedy. Even in deep-seated caries it frequently answers an excellent purpose, promptly allaying the excessive pain, and promoting the absorption of effused fluids. As soon as evident fluctuation exists, or even before, if there be inordinate tension and throbbing, a free incision should be made, extending, if possible, into the very depths of the bone, so as to admit of the most thorough drainage. To allow the matter to remain pent up always proves excessively injurious, from its tendency to burrow among the surrounding structures, detaching them from each other, and leading, in the end, to the formation of numerous sinuses. Besides, the early evacuation of the matter greatly abridges the suffering, constitutional as well as local, and thus prepares the system better for the future struggle. When the matter is lodged in the interior of a bone, as, for instance, the extremity of the femur or tibia, evacuation should be effected with the trephine.

The means now described are all merely of a palliative nature; they relieve pain, swelling, and constitutional disturbance, but cannot cure the disease, however slight. To fulfil this indication, other remedies are necessary; some for modifying the affected tissues, so as to afford them an opportunity of regaining their normal characters, and others for effecting riddance of the diseased bone either in part or in whole.

Under the first head may be mentioned various detergent and acidulated preparations, as solutions of the chlorides, creasote, nitrate of silver, and acetic, nitric, and hydrochloric acid, their strength varying with the age and constitution of the patient, and the state of the parts, the contact being effected by means of a large glass syringe, repeated twice in the twenty-four hours. The chlorides are particularly serviceable in these cases, on account of their cleansing and deodorizing effects, while the acids act more directly upon the osseous tissue, stimulating the capillary and absorbent vessels, and thereby promoting a more healthy tone, at the same time that they produce disintegration of the earthy matter of the diseased bone. These remedies, and all others of a kindred nature, are certainly not without some benefit in the milder and more accessible cases of caries, but they all have the disadvantage of being difficult of application, as well as uncertain in their results, and can rarely be relied upon for a cure. I have, therefore, of late years, entirely abandoned their use with this intention, and now employ them only with a view to their detergent and deodorizing effects, preferring, of course, the chlorides to any of the other articles for this purpose.

The actual cautery, formerly so much vaunted in the treatment of certain forms of caries, especially in that of the carpal and tarsal bones, is obnoxious to the same objections as the remedies just mentioned. In applying it, it is necessary not only to divest the affected bone thoroughly of its soft parts, but to employ the greatest circumspection, otherwise a much larger amount of tissue may be destroyed than is desirable. Moreover, the eschar is always a long time in coming away, and the iron has generally to be used again and again before a cure is finally effected.

In the treatment of caries of the deeply-seated bones, Dr. Fitzpatrick enlarges the sinuses with the Vienna paste, and after having pierced the exposed bone with a strong knife, inserts the caustic into its interior. I have had no experience with this practice; but regard it as even more objectionable than the application of the actual cautery.

Under the second head are included the operations necessary for scraping or cutting away the diseased structure, excising the affected bone, either in part or in whole, and amputating the affected limb, when the case is unmanageable by other means.

All operative interference, having for its object the removal of the carious matter, is, as a rule, carefully abstained from until the disease has become strictly chronic, or, in some degree, ceased to spread. If this injunction be disregarded, injury and not benefit will be certain to follow, the irritation excited by them giving new impetus to the morbid action. The precise time for interference cannot, of course, be specified, but it is evident that no attempt should be made to scrape or cut the bone so long as the superimposed parts are very tender, tumid, and inflamed. The proper treatment, in this condition,

consists in the use of leeches, medicated fomentations, and other antiphlogistic measures designed to soothe the irritated structures, and prevent the spread of the disease.

When the caries is of small extent, it may generally be removed by means of a burr-head drill, similar to that used by the dentist for scraping away caries from decayed teeth previously to plugging. With such an instrument, of which the adjoining sketch, fig. 376, affords a good idea, the whole of the diseased substance may be cut away in a few minutes,

Fig. 376.　　　Fig. 377.　　　Fig. 378.　　　Fig. 379.　　　Fig. 380.
Instruments for removing Carious Bone.

with little pain to the patient, and no detriment whatever to the neighboring parts, which should always be turned aside immediately prior to the operation. Every bone-case should have from three to six drills, of varying size and shape, so as to meet every contingency that may arise in practice. Several trephines, pliers, gouges, chisels, and scrapers should also be at hand. In operating upon the tarsal and carpal bones, a short, stout scalpel, with a rather sharp convex extremity, and a large handle, will generally be found to be very desirable. Such an instrument is peculiarly advantageous in paring the surface of deep-seated cavities. When the ligaments and cartilages are involved, dissection can hardly be completed in a satisfactory manner without a pair of blunt-pointed scissors, with long, thick, narrow blades. The raspatory is useful in smoothing carious cavities after the removal of the disorganized substance. During the operation the diseased cavity is kept free from blood by means of the elastic bandage and of sponge mops.

When all the diseased structure has been removed, the affected cavity should be thoroughly washed out with a syringe. Unless this be done, more or less of the bony matter will be left, thus keeping up irritation and discharge, and interfering with the reparative process.

Considerable hemorrhage often attends these operations, the blood either proceeding from small arteries, or oozing from numerous points. In the former case the ligature will usually be required, more particularly as the vessels are unable to retract on account of the indurated condition of the surrounding parts, while in the latter the temporary application of the sponge wrung out of hot water will commonly speedily arrest the flow. If this do not answer the purpose, the bleeding cavity must be stuffed with lint soaked in a strong solution of subsulphate of iron, the plug being retained until it is loosened by the suppurative process.

Doubt is often experienced, in these operations, as to the amount of substance to be removed, the precise line of demarcation between the sound and diseased structures

not being always easy of determination. A good diagnostic, under such circumstances, is to wash the fragments in water, when, if they are carious, they will exhibit a whitish, grayish, greenish, or blackish appearance; whereas, if they are healthy, they will be found to be vascular and red, and to retain their normal consistence, presenting none of the fragile and porous characters which distinguish them in the former case.

Bleeding having been arrested, the edges of the wound are loosely approximated by suture; and the limb, placed in a favorable position for drainage, is inclosed in a bandage, the affected parts being covered with lead water dressing. Occasionally a tent is needed to conduct off the matter, and prevent premature closure; and for some time the bony cavity should be injected twice or thrice daily with tepid water and castile soap, or some gently detergent lotion. The great sources of danger after the operation are erysipelas and pyemia.

Fig. 381.

Structure of a Granulation in a Bone.

The healing process, after such an operation, is attended by the development of granulations, which, under the microscope, display very much the same appearances as those of the soft parts. The vessels, as shown in fig. 381, from a drawing made for me by Dr. Packard, have a remarkably looped and varicose arrangement. The specimen was taken from an ulcerated patella, which was covered by an immense number of beautiful scarlet granulations, hardly the size of the smallest pin's head, closely grouped, and exceedingly tolerant of rude manipulation. The section was magnified sixty diameters.

Excision of an entire bone is sometimes necessary for the relief of this disease. Such a procedure is most frequently required on account of caries of the carpal and tarsal bones, upon which it is frequently performed with great advantage, a useful limb being generally left even after the removal of several of these pieces. In the long bones, the operation is usually limited to the articular end, or to this and to a portion of the shaft. Respecting the manner of executing this operation, and the estimate to be placed upon it, in a curative point of view, special mention is made in the chapter on excision.

When the disease is so extensive as to be uncontrollable by the means now described, and the attendant discharges are so copious as to give rise to profuse night-sweats, marasmus, and colliquative diarrhœa, amputation of the limb, comprising the carious bone, affords the only chance of safety, and should be performed without delay. It is surprising how the system usually rallies after such an operation. The patient, in the course of a few days, generally looks like a new being; his sweats and diarrhœa soon leave him, and he rapidly improves in health and spirits, making often an excellent recovery.

SECT. IX.—NECROSIS OR MORTIFICATION.

The word necrosis denotes the death of a bone, and is strictly synonymous with mortification, gangrene, or sphacelus, used to designate the death of a soft structure. The immediate cause of the occurrence is inflammation, eventuating in an arrest of the circulation and innervation of the osseous tissue.

Necrosis is most common in the superficial bones, or in those which lie immediately beneath the integument, as the tibia, ulna, lower jaw, clavicle, femur, and the phalanges of the fingers. The long bones suffer more frequently than the short, and the short than the flat, the reverse being the case in caries, for the reason that, in the former, the compact tissue is most commonly affected, and in the latter, the spongy.

Children under fifteen years of age, of a strumous diathesis, or a syphilitic taint, are the most common subjects of this disease. Of the influence of sex, climate, and occupation, upon its production, nothing satisfactory is known. It has generally been supposed, and not without reason, that it is most common in cold, damp, and variable regions, on the assumption that the inhabitants of these countries are particularly subject to suppression of the cutaneous perspiration, which, in individuals predisposed to disease, may, it is alleged, readily cause death of the more superficial bones. Persons engaged in the manufacture of lucifer matches are liable to necrosis of the jaw, from

the contact of the fumes of phosphorus with the interior of decayed teeth; and it is not improbable that there are other pursuits which may conduce to destructive inflammation of the osseous tissue, although of their precise nature and mode of action we are not informed.

Causes.—The idiopathic form of necrosis will be found, as a rule, to be most common in young subjects whose constitution has been hereditarily damaged, or who exhibit well-marked evidence of the scrofulous diathesis, as evinced by the delicacy of the skin, the languid circulation, the tumid belly, and the deficient temperature of the extremities. This has certainly been the case in the great majority of instances that have come under my own observation, and I believe that my experience, in this respect, in the main, agrees with that of other writers. It is in persons of this description, more particularly, that we so frequently meet with the worst species of necrosis of the tibia, femur, and humerus, telling so fearfully upon the constitution, and so often requiring amputation in order to save the patient's life. The most common exciting cause of the disease, in this class of subjects, is exposure to cold, as when a boy, overheated by play, sits down in a current of air, and thus suddenly repels his perspiration; or when, under similar circumstances, he strips himself and plunges into cold water. Not aware, perhaps, for several days that he has sustained any injury he is suddenly seized, not unfrequently while asleep, with violent pain in one of his limbs, attended with severe rigors alternating with flushes of heat, and, upon examining the affected part, he observes that it is exquisitely tender on pressure, more or less swollen, and covered with an erysipelatous blush. The local and constitutional symptoms progressing, matter soon forms deeply beneath the muscles, the swelling becomes more and more circumscribed, and, ulceration taking place, the contents of the abscess gradually find their way to the surface, leaving the bone dead below. Such is the manner in which necrosis is generally produced in weakly, scrofulous subjects, and it is hardly necessary to add that all the attendant phenomena are indicative of a rapidly destructive osteitis, osteomyelitis, or osteitis and periostitis.

Tertiary syphilis is another cause of necrosis, and the history of this disease shows that the osteitis growing out of it is more liable to occasion death of the bone when the patient has been subjected to free courses of mercury for its cure, than when the affection has been treated on general antiphlogistic principles. The two poisons coming together, and mingling their baneful influence, induce a form of inflammation which is extremely prone, especially in persons of a worn-out, debilitated constitution, to terminate in gangrene of the bones, particularly those of the nose, palate, upper jaw, leg, and arm.

Protracted courses of mercury, especially in young subjects of a strumous diathesis, or exhausted by diarrhœa, cholera, or eruptive diseases, often cause necrosis of a frightful character, generally of the maxillary bones, but sometimes, also, of other pieces of the skeleton. What is termed dry salivation is frequently more destructive to the gums, teeth, and jaw-bones than salivation accompanied by profuse discharge. The debility provoked by the injudicious use of drastic purgatives and tartar emetic has occasionally eventuated in necrosis of some of the bones of the head, trunk, and extremities. Scurvy has been known to produce similar effects, although more commonly it causes caries. In short, there is reason to believe that idiopathic necrosis may be induced by whatever has a tendency to bring about an impoverished condition of the blood and solids.

Among the local causes of necrosis the most common are wounds, contusions, fractures, amputations, and chemical irritants. In the tibia and femur, the probability is that mere concussion, as happens when a person falls from a considerable height and alights upon his foot or knee, is often sufficient to produce a destructive form of osteitis. Gunshot injuries are a frequent source of the occurrence, whether the bone is merely grazed by the passage of the projectile, or whether the ball lodges in its substance and acts as a foreign body. Partially detached splinters frequently perish under such circumstances. Mere denudation of a bone, however occasioned, is often followed by its death, especially when the loss of periosteum is very considerable, or if, even when it is comparatively trivial, it is accompanied by the laceration of the nutrient artery, or extensive destructive of the soft parts generally. In this condition, the necrosis is usually limited to the outer compact structure, the part ultimately coming away in the form of an exfoliation. Such an event, however, is by no means inevitable. The periosteum may be stripped off to a considerable extent, and yet, if the bone is in other respects healthy, or enjoys a tolerably active circulation, granulations will spring up, and thus gradually repair the breach. It is only when the vascular connection between the two structures has been materially impaired, or totally destroyed, that necrosis will be likely to ensue, the bone becoming white and

dry, and ultimately dark and even black. These appearances are well illustrated in what so often happens in compound fractures, attended with protrusion of the end of the bone divested of its fibrous covering, and in the phalanges of the fingers in whitlow.

Death of bone is occasionally produced without the intervention of inflammation, from mere shock, contusion, or compression of the component elements of the osseous tissue, and the sudden arrest of the circulation from obstruction of its vessels, however induced. Embolism probably plays an important part in the causation of such cases, just as it sometimes does in mortification of the soft parts, and, occasionally, again the trouble may be due to the rupture of the nutrient artery.

Necrosis may be partial or complete, simple or complicated, superficial or deep ; that is, it may be limited to a portion of a bone, or it may pervade its entire thickness. It is seldom that an entire bone perishes. Such an occurrence is sometimes observed in the carpus and tarsus, in consequence of external injury, but it is extremely uncommon in the long bones ; in these the shaft alone generally suffers, the articular ends retaining their vitality. Necrosis of the whole lower jaw has been repeatedly noticed as a result of the action of phosphorus, and some interesting cases in which the entire bone was successfully removed on account of this disease have been related by Dr. Carnochan, Dr. J. R. Wood, and others. Finally, necrosis may be limited to the outer surface of a bone, involving merely its superficial lamellæ, the dead portion being ultimately detached in the form of a thin scale or plate ; or it may invade its entire thickness, and it then not unfrequently begins in the very depths of the cancellated tissue, generally from injury or disease of the medullary membrane.

The occurrence of necrosis, the elimination of the dead bone, usually called the sequester, and the formation of new bone as a substitute for the old, or that which has died, involve some very curious pathological and physiological processes, deserving of attentive consideration. The symptoms which immediately precede, and those which accompany the death of the bone, are generally such as are denotive of violent inflammation, deep-seated, attended with excruciating pain, and rapidly tending to the suppurative crisis, the mischief being often done in a few days, or even in a few hours. Action, general as well as local, is excessive, and both the part and system occasionally fall a prey to its devastating influence, especially when there is involvement of a large neighboring joint, as now and then occurs when the necrosis attacks the inferior extremity of the femur, and extends into the knee. Progress, however, is not always so swift and overwhelming ; often it is quite the reverse, the parts and system suffering but little, and the malady pursuing apparently a chronic course.

A very common way in which the occurrence of gangrene of a long bone is announced is this. The patient, usually a lad from six to ten years of age, after having been over-heated or exposed to severe cold, retires at night apparently perfectly well, but towards morning he is aroused by pain in the thigh or leg, deep-seated, circumscribed, of a sharp, aching character, and so excessively severe as to deprive him of further sleep and rest. The soft parts over the seat of the disease soon become exquisitely tender to the touch, swollen, and discolored, the surface having a glazed, dusky, reddish, or purplish tint, and pitting under pressure from the infiltration of the subcutaneous connective tissue. These local phenomena are always attended by severe constitutional disturbance. There is high, raging fever, with a tendency to delirium, and excessive restlessness ; the pulse is full, hard, and frequent ; the skin is hot and dry ; the thirst is incessant ; and the urine, thick and scanty, is surcharged with lithic acid. By and by, violent rigors set in, succeeded by flushes of heat, the pain assumes a tensive, throbbing character, the swelling becomes more diffused, extending often to a great distance up and down the limb, as well as widely circumferentially, the discoloration acquires an erysipelatous blush, and a careful examination soon detects, what, indeed, the existing symptoms sufficiently declare, the presence of pus, deep-seated, lying partly between the affected bone and the periosteum, and partly on the outside of the membrane, in the connective tissue of the muscles and aponeuroses, which it often extensively dissects and separates from each other, forming large pouches from which it is frequently difficult to dislodge it. Sometimes the abscess opens into a neighboring joint, and thus becomes a source of additional mischief, exciting inflammation in the synovial membrane, perhaps ultimately followed by destructive softening of the cartilage, and caries or necrosis of the end of the bone.

The quantity of matter at this stage of the disease varies from a few ounces to upwards of a pint, and is mostly derived, not from the affected bone, or bone and periosteum, but from the soft parts in their immediate vicinity, which always freely participate in the morbid action. In spontaneous necrosis, it is usually of a strumous character, of a yel-

lowish color, verging upon greenish, more or less fetid, especially if long retained, and of a thick, cream-like consistence, interspersed with curdy substance, and, not unfrequently, also with shreds of dead connective tissue. Occasionally the matter is thin, ichorous, or sanious, but such an occurrence is unusual until after the bursting and the evacuation of the abscess.

When the matter has been discharged, whether spontaneously or artificially, there is always a marked improvement in the symptoms, both local and constitutional, and an opportunity is now afforded for a thorough examination of the parts. The best instrument for this purpose is the finger, or, when the opening is very small or devious, the probe. With either of these it is generally easy to determine the extent of the destruction of the periosteum, and the amount of injury sustained by the bone, the surface of which will generally be found to be more or less rough, and of a whitish, grayish, or ashy hue, without any appearance whatever of vascularity.

Such is a succinct account of the circumstances which precede, accompany, and follow the ordinary occurrence of necrosis. The first stage of the disease is over: the matter consequent upon the inflammation has been discharged; and the inflammation itself has measurably subsided, although the soft parts are still swollen, indurated, tender, painful, and disabled. Nature, never idle, now begins the double work of elimination and repair, both usually very tardy, often imperfect, and sometimes altogether unsatisfactory, the powers both of the part and system being inadequate to accomplish the object. In gangrene of the soft structures, the separation of the eschar is generally an easy matter compared with that of a bone, provided the patient's strength holds out; the process, once fairly commenced, proceeds rapidly and energetically, the surgeon each day seeing decisive evidence of the fact; soon the line of demarcation between the dead and living parts is perceived; then granulations spring up in the intervening chasm; and, finally, the reparative efforts still advancing, the breach is gradually closed over with new skin, a circumstance clearly denotive of the completion of the cure. But it is altogether different in necrosis; here the detachment of the slough is a matter of time, requiring many weeks, if not several months, for its satisfactory conclusion, and even then generally demanding the interference of art before it can finally be effected. The cause of the difference is sufficiently obvious. In the one case there is an active circulation and an energetic system of absorbents, the former furnishing an abundance of plastic material for the repair of the lost tissues, and the latter exerting themselves to cast off the dead substance; in the other, on the contrary, everything is the reverse, and the parts labor under the additional disadvantage of being loaded with earthy matter, which is obliged to be softened and disintegrated before it can be removed by the vessels whose duty it is to get rid of it.

Fig. 382.

Sequester of the Tibia.

The necrosed substance may, as already stated, embrace merely a portion of the periphery of a bone, as, for example, its outer layer; or it may include its entire thickness, and also the greater part of its length. In the former case it constitutes, when detached, what is called an *exfoliation*, in the latter a *sequester*, a distinction of considerable importance, not so much on account of the extent of the dead substance, as of the manner in which the breach of continuity is repaired, or a new bone formed.

An exfoliation is commonly merely a thin scale, plate, or lamella of the outer, peripheral portion of a long bone, of variable color, and consistence. In general it is either whitish, grayish, or of a light brownish hue, rough, more or less porous, very brittle, and in great measure deprived of animal matter.

A sequester, properly so called, varies much in size and shape, consisting, at one time, of a part only of the circumference or length of a bone, and, at another, of its entire shaft, with perhaps a portion of its articular ends. The adjoining sketch, fig. 382, from a preparation in my collection, represents a very common form; it was a part of the body of the tibia, in which all the spongy structure is completely destroyed, while the compact is remarkably hard and firm. A dead bone, as a rule, is rough, pitted, or excavated, seldom perfectly smooth, spiculated at the extremities, of a grayish, brownish, or blackish color, and emitting when struck with a probe or piece of metal, a peculiar hollow sound, by which it is usually readily distinguished from healthy bone. In the cylindrical pieces, as in the femur and tibia, it is generally dense and dry; in the short and flat, porous, moist, brittle, and easily crumbled. The analyses of Von Bibra show that there is a very

great reduction of organic matter in necrosis, with a corresponding increase of earthy, the latter forming as much as eighty per cent. of the entire mass. The same experimenter has ascertained that the difference is considerably less in the acute variety of the lesion than in the chronic.

Bone recently dead, or bone in a dying condition, before the establishment of the eliminating process, is generally of a dirty grayish, greenish, or brownish color, more or less moist, and excessively fetid, the odor resembling the stench of a macerating tub. In rare cases it is of a purple, lilac, or blackish hue, especially when the devitalization has been preceded by deep congestion, or congestion and ecchymosis, of the osseous structure. When a bone perishes very suddenly, the affected part is comparatively dry, and free from smell.

Necrosis of the articular extremity of a bone does not differ essentially from that of its shaft. It may be superficial, as when it affects the articular surface alone; deep-seated, as when it occurs in the cancellated structure; or universal, as when it invades the entire thickness of the extremity. However this may be, it is always accompanied by inflammation of the synovial membrane, or of this membrane and of the articular cartilage, and is very liable to be followed by permanent ankylosis. The joint is swollen and indurated, excessively painful, pierced by sinuses, and the seat of more or less profuse discharge of unhealthy matter. The affected bone itself is generally remarkably soft, saturated with sanious fluid, and of brownish, grayish, or slightly greenish color. The disease is most frequent in young, scrofulous children, and after gunshot, railway, and other severe injuries.

When necrosis occurs in the spongy structure of an articular extremity, the sequester may be so firmly incarcerated in the interior of the bone as to render it difficult of access. Sometimes the entire extremity perishes, as is exemplified in the head of the thigh-bone in coxalgia, in the condyles of the femur after gunshot and other injury, and in strumous or syphilitic disease of the head of the humerus. In a case of necrosis of the latter bone, in a lad ten years of age, recently under my care at the College Hospital, the head of the bone had entirely disappeared; and a similar fate is occasionally experienced by the corresponding portion of the femur.

In what is known as *dry necrosis*, a rare affection, there is an entire absence of suppuration, the bone being free from moisture, and of a brownish or dark grayish color. The disease, originally described by Stanley, in 1849, has since been noticed by Baker, Sir James Paget, and other observers, chiefly in the long bones, and is, in every respect, analogous to senile gangrene of the soft structures, the osseous tissue gradually dying in consequence of disordered circulation interfering with a due supply of blood, and followed by chronic inflammation. The sequester, in such cases, is usually slow in separating, and so firmly imprisoned by the new bone as to render it extremely difficult to remove it. In some cases a portion of endosteum retains its integrity, and thus two involucres are formed, one by this membrane, and the other by the periosteum; but such an occurrence is uncommon.

Mode of Repair.—While the adjacent living bone is engaged in detaching the dead bone, with a view to its ultimate expulsion, the latter acts as a foreign body, and sets up mild inflammatory changes in the periosteum, the soft layer of which proliferates, becomes embryonic, and furnishes the material for the formation of the substitute or new bone, the process by which this is accomplished being similar to that which presides over the creation of the original structure, the period required for the completion of the development varying, according to the age and vigor of the patient, and the character and amount of the local disease, from a few weeks to several months. The new bone is at first a mere shell encasing the old, and thus serving to separate it from the surrounding parts, which ill brook its presence. In time, however, it increases in thickness, being often from three to six lines in depth, and occasionally it is fully as large as the original piece. Its surface is usually somewhat rough, and it is not uncommon to observe upon it considerable eminences

Fig. 383.   Fig. 384.

Necrosed Tibia, the dead Bone lying loose within the New.

Cloaca in a necrosed Tibia.

and depressions, owing evidently to the irregularity of the developmental process. The new substance, too, has comparatively little areolar tissue, and, therefore, especially if some time has elapsed since its formation, it is always cut with great difficulty, the resistance offered by it being much greater than that of the preëxisting structure. In cases of long standing, indeed, it often acquires the solidity and density of ivory, so that it requires great patience and perseverance to penetrate it with the saw and pliers. The vessels, in this event, are always very small and sparse, and the Haversian canals are traced with difficulty. In the long pieces, after the death and removal of the shaft, there is never a complete reproduction of the medullary canal and its lining membrane, or of the endosteum. In fact, the new bone, although it possesses all the essential attributes of the osseous tissue, is, nevertheless, a very imperfect type of the original, and, therefore, much less capable of resisting the effects of disease and accident. The appearances of the new bone, encasing the old or dead, are admirably depicted, in fig. 383, taken from a specimen in the collection of the late Professor Pancoast.

In viewing the new bone as it surrounds the old, its surface is found to be pierced by several apertures, to which, from their fancied resemblance to the rectal pouch of a bird, the term *cloacæ*, fig. 384, is usually applied. These openings, which play an important part in the expulsion of the dead bone, owe their existence to a deficiency of periosteum, or of secreting structure, as is proved by the fact that, when the formation of new osseous tissue goes on uniformly around every portion of the periphery, the old bone will be completely imprisoned, thus not only obscuring the diagnosis, but rendering the removal of the sequester a matter of great difficulty and perplexity. The size of these cloacæ varies, in different cases, from that of a three-cent piece to that of a quarter of a dollar, their shape being generally rounded, or somewhat oval. Not unfrequently, however, they occur in the form of long, irregular fissures, or slits. Their number is indefinite; sometimes there is but one, while at other times there may be as many as half a dozen, the latter number being by no means uncommon in necrosis of the shaft of the tibia. However this may be, they always communicate with the surface of the limb in which the affected bone is situated, the passages between them constituting so many channels for the discharge of matter and the ultimate elimination of the sequester, although, owing to the inadequate dimensions of the cloacæ, this is seldom effected without the intervention of art. It is an interesting fact, of no little practical value, that these openings are always situated in that portion of the new bone which is least covered by soft parts. After the removal of the sequester they generally disappear under the development of new osseous matter.

There has been much dispute among pathologists as to the agents by which the new bone is produced. Without entering into any details, I may state, as the result of personal observation, that the perfection of the new bone will generally be in proportion to the integrity and activity of the periosteum. I have always found that, when this membrane has suffered much during the inflammation which precedes and accompanies the necrosis, the reproductive process, or new osseous epigenesis, is tedious and difficult, and often extremely inadequate, the new bone being comparatively small and stunted, and, therefore, ill adapted to answer the purpose of a substitute bone. The part which the periosteum plays in the development of the new bone is well shown in the formation of cloacæ, which, as already stated, is clearly dependent upon the partial destruction of that membrane. If the periosteum everywhere retained its integrity, the new bone would be without a solitary opening, and, consequently, the sequester, or slough, would be an encysted body, imprisoned, as it were, in a closed canal. When this membrane has perished along with the bone, as occasionally happens in the shaft of the tibia or femur, the new bone will be formed by the surrounding structures, whatever these may be, but it will be so short, thin, and imperfect as hardly to deserve the name of substitute, to which, in general, it is so well entitled.

When the eschar presents itself as an exfoliation, or as a thin, superficial scale, the breach is repaired through the medium of granulations, which, being derived from the old bone, are extremely vascular and sensitive, and soon assume the ossific process, throwing out an abundance of proper material for the accomplishment of the object. A similar process is set up when the central portion of a bone perishes; for here, the endosteum being also destroyed, it can have no agency in the reproductive act. When this membrane retains its vitality, it must necessarily exert an important influence as an osteogenic agent.

The idea has been broached, and warmly defended, that when the shaft of a bone is necrosed, so as to leave merely its articular ends, the new bone is formed exclusively by these ends, the osseous matter extending gradually towards the middle of the chasm, and

ultimately coalescing there. Such a theory, however, is wholly untenable, as it is contrary to what occurs in the growth of the original bone, which always takes place by several distinct points, one of which is invariably central. However well the surviving extremities might perform their duty, yet, as there is no central nucleus, serving as a point of departure for the ossific matter, it is easy to conceive that the bone would always necessarily be so deficient at that particular spot as to disqualify it materially for the performance of any useful functions.

Although the osteogenic properties of the periosteum, have long been familiar to the surgeon, through the labors of Troja, Koehler, Weidmann, and other observers, new light has been thrown upon the subject by the admirable and exhaustive experiments of Dr. Ollier, of Lyons, since confirmed by other observers. He found that, in rabbits, portions of this membrane, completely detached from the bone, might be pushed into the soft structures, and still preserve their power of generating osseous matter. In some cases, indeed, this faculty was not lost when the periosteum was transplanted to remote parts of the body, or from one animal to another. The results of these researches, however, although pathologically interesting, possess little, if any, practical value, inasmuch as they cannot be rendered available in the human subject.

Symptoms.—The symptoms attendant upon necrosis, in its earlier stages, have already been pointed out; those which accompany the separation of the old bone and the formation of the new, are, in general, sufficiently characteristic. The most important of these are, little ulcers, surrounded by large, unhealthy granulations, arranged in a papilla-like manner; sinuses leading from these ulcers down to the dead bone; and a discharge, more or less constant and copious, of thin, fetid, sanious matter, or of thick, white, inodorous pus; accompanied, in all cases, by a certain amount of hardness and swelling, pain and tenderness on pressure, wasting of the soft parts above and below the seat of the disease, and marked impairment of the functions of the neighboring joints. The general health always suffers; the patient is wan and emaciated; and, if the irritation is at all extensive, there will usually be hectic fever. In some cases the end of the sequester protrudes at one of the cloacae, thus at once declaring the true nature of the complaint; but, more commonly, the dead bone is completely imprisoned by the new, and can only be reached by the probe or finger, carried along the sinuses leading from the surface to the cloacae. In order to ascertain whether the separation has been effected, or whether the dead bone still maintains its relations, in some degree, with the living, the surgeon may often advantageously use two probes, introducing one at each extremity of the eschar, and moving them alternately in different directions, as may frequently be easily done when the detachment is complete. In general, also, useful information, in this respect, may be obtained from a consideration of the history of the case, as the size of the affected bone, the age of the patient, and the commencement of the attack. Thus, other things being equal, it will usually be found that a small bone will be more readily separated than a large one, and the bone of a young subject than that of an old one, while in every instance the process may be supposed to be more advanced in proportion to the period that has elapsed since the death of the bone.

A sequester or loose piece of bone occasionally causes serious mischief by its pressure upon neighboring structures, especially the nerves and bloodvessels, giving rise, perhaps, on the one hand, to severe neuralgia, and on the other, to more or less copious hemorrhage. The latter accident is most likely to occur from erosion and perforation of the popliteal artery in necrosis of the lower extremity of the femur; but it has also been met with in the anterior tibial artery, and even in the artery of the tongue, in connection with necrosis of the lower jaw.

Prognosis.—The prognosis of this disorder is variable. In general, it may be considered to be favorable when it is owing to external or local causes; when it is confined to the outer portion of a bone, the necrosis occurring in the form of an exfoliation; when it is simple and of moderate extent; and when the patient is young, robust, and of good constitution. On the other hand, the cure is difficult, and the issue doubtful, when the disease is acute, extensive, or complicated with other affections; when it attacks pieces which are of high importance on account of their function or situation, as those of the skull; when it occupies the interior of a bone, and involves several parts of it; when it arises from an internal or constitutional cause, as struma or syphilis; when it extends into the adjacent joints, especially when they are of large size; and, lastly, when the patient is enfeebled by age, long suffering, or previous disease. The most common causes of death are erysipelas, pyemia, and profuse discharge.

The time required for the separation of the eschar and the development of the sub-

stitute bone will depend, as already stated, in great measure, upon the situation and extent of the disease, the age, health, and the condition of the patient, and various other circumstances not admitting of definite statement. That the whole of a necrosed bone may be regenerated is a fact so well established as not to admit of any doubt. The new bone, however, as intimated elsewhere, is always, at best, only an imperfect copy, although, as regards its functions, it usually answers the purpose well enough, both as it respects its length and thickness, especially the former, which is usually equal to the old, or the original piece. When the substitute bone, during its development, is subjected to strong muscular contraction or made to bear too heavy a weight, it is very apt to become crooked, and hence all such mishaps should be carefully guarded against.

Treatment.—Although the treatment of necrosis must of necessity depend very much upon circumstances, there are three indications which deserve special attention; the first is to limit and moderate the inflammation which is the immediate cause of the mischief, the second, to watch nature during the separation of the old bone and the formation of the new, and the third, to promote the removal of the sequester, slough, or eschar.

The first of these objects is to be attained by the proper employment of antiphlogistic remedies; by the lancet, if the patient be plethoric, laxatives, antimonial and saline medicines, light diet, repose, and the free use of opiates to allay pain and induce sleep. The affected parts, placed in an easy, elevated position, are leeched and fomented, or, what is particularly serviceable, painted with a strong solution of iodine at least three times in the twenty-four hours, the surface being protected in the intervals with an emollient, anodyne cataplasm, or medicated water-dressing. In some instances, great benefit is derived from the application of a blister large enough to encircle nearly the whole of the affected limb, and kept on sufficiently long to produce vesication. By these means, the surgeon not only limits the inflammation, but promotes the absorption of effused fluids, and hastens the suppurative crisis, which is always inevitable, to a greater or less degree, in every case of this kind. As soon as fluctuation is perceived, or even before, if there be inordinate pain and tension, or deep-seated matter, a large incision is made at one or more points, in the direction of the long axis of the bone, in the hope of saving osseous as well as soft tissue, especially the periosteum, the integrity of which is so essential to the development and formation of the substitute bone. In making the opening, due attention is, of course, given to drainage, and to the prevention of its premature closure.

The second indication is to watch the part and system during the sloughing process and the stage of repair, to enable them to bear up under the trying ordeal. The case requires active vigilance rather than active treatment; care, on the one hand, that the disease do not spread, and, on the other, that the debility consequent upon the drainage and irritation do not obtain the mastery, and so bring on fatal exhaustion. A certain amount of inflammation must necessarily attend both operations, and, therefore, action must not be too much repressed, lest nature be thwarted in her efforts. A nutritious diet will generally be required, and the patient will often be immensely benefited by animal food and milk-punch, ale, porter, or wine, and the use of quinine, iron, and aromatic sulphuric acid, especially if there be hectic fever and night sweats. Gentle exercise should, if the strength will permit, be taken daily in the open air upon crutches; or, if this be impracticable, he should be pulled about in a hand-car, or swung in a hammock. Attention is, of course, paid to the bowels and secretions. Pain is allayed with anodynes. The principal local remedies are leeches, provided there is any disposition to overaction, the daily application of iodine, and the use of the bandage to support not merely the affected parts, but also the distal portion of the limb, which, when this precaution is neglected, has usually a tendency to become œdematous. Fetor is allayed, and discharge moderated, with chlorinated sodium or permanganate of potassium, introduced with the syringe and sprinkled upon the dressings. Much has been said about the employment of solvents, thrown in through the principal sinuses upon the dead bone, in the hope of promoting its gradual disintegration and elimination. Special stress used to be laid upon various acid solutions, particularly the nitric, hydrochloric, and pyroligneous; but experience has proved that they are always productive of harm, from their irritating effects upon the new bone and the soft parts, whilst, unless they are intolerably strong, they can exert no destructive influence upon the sequester itself. If such lotions be employed at all, they should, therefore, be employed in the mildest possible form, simply with a view to their detergent and alterant effects, which are often very salutary, expediting the sloughing and restorative processes. In general, however, all the good that can be expected to result from such remedies may be accomplished by injections of tepid water, impregnated with castile soap, a little potassa, or common salt, followed, if there be much fetor, by a weak solution of

some deodorizer. If new abscesses form, they must, as already mentioned, meet with prompt attention.

During this stage, a stage of comparative inactivity, inquiry is made into special diatheses, or states of the system. The patient, if strumous, may be in need of special remedies; or his system may be impregnated with the syphilitic poison, and a course of mercury, or of iodide of potassium, may be required. It must be obvious that no satisfactory progress can be made towards a cure so long as the system is borne down by a vitiated state of the solids and fluids.

The third indication is to get rid of the sequester, for so long as this remains it must necessarily keep up inflammation and discharge, the latter of which is generally not only highly offensive, but often so copious as to establish a serious drain upon the system. It was commonly supposed, until recently, that the dead bone, during its sojourn among the living tissues, was acted upon by the absorbent vessels, so as materially to diminish its size and weight, the idea having, apparently, derived support from the altered and pitted condition of the surface of the affected piece. This notion, however, was completely dispelled by the experiments of Mr. Gulliver, who ascertained, as might, indeed, have been anticipated, that such an occurrence is altogether impossible. Portions of necrosed bone, carefully weighed before and after exposure, were confined on suppurating surfaces, in the medullary canal, and in the subcutaneous connective tissue, for months, and in one instance for upwards of a year, without undergoing the slightest alteration whatever.

Inasmuch, then, as the dead bone acts as an extraneous body, and is no wise amenable to the agency of the absorbents, the indication plainly is to remove it by operation. Such a step is the more imperative because of the manner in which it is imprisoned, the substitute bone forming a firm, solid case around it, and thus effectually preventing its extrusion. The only circumstance which should make the surgeon at all hesitate is the doubt that may arise in his mind respecting the probability of the dead bone being completely detached, and the new one sufficiently advanced to enable it, after the removal of the sequester, to maintain its position without bending under the weight of the limb, in turning in bed, walking, or sitting. If he is satisfied of this, as he usually may be after a careful examination, the operation should at once be proceeded with. The instruments that will be required are several scalpels, a trephine, a Hey's saw, an elevator, pliers, chisels, gouges, and stout forceps, with a good syringe for washing away osseous débris. The adjoining cuts represent some of the more important of these instruments. Bonwill's surgical engine often affords valuable aid in operations on the bones. The different steps of the procedure will be greatly facilitated by the use of the elastic bandage, which, while it effectually prevents bleeding, enables the surgeon to do his work more rapidly and more thoroughly.

The incisions should be made in the direction of the long axis of the bone, out of the way of the great vessels and nerves. The best plan is usually to select one of the principal cloacæ, or, when two or three are close together, especially if they are on the same plane, to connect them, thereby affording more room to work in. When the soft structures are much diseased, they may be included in an elliptical incision, as, in this event, it may be best to get rid of them. When it is deemed advisable to connect two or more cloacæ, the object may easily be attained by a Hey's saw, the circular saw of the surgical engine, or, if the new bone is not very thick and firm, by the pliers. The trephine is chiefly of use when the openings in the substitute bone are very small, or when this bone possesses unusual density and thickness, rendering its division extremely difficult by the more ordinary instruments. Access having thus been obtained, the sequester is to be seized by one of its extremities, with a pair of forceps having long, thin blades, serrated on their inner surface, and from a third of an inch to half an inch in width, the handles being well curved, so as to facilitate prehension and maintenance. In executing this step of the operation great care must be taken not to press the extremity of the sequester into the soft parts, on account of the danger of wounding important vessels and nerves. Such a precaution is especially important in removing dead bone from the lower end of the femur, on account of the proximity of the popliteal artery.

When the sequester is unusually long, it may be necessary to bisect it, and extract each piece separately; an operation which is always easily performed with the pliers or chisel.

The dead bone having been removed, the next step is to scrape away the semiorganized granulations from the inner surface of the new bone, and to wash out the canal with the syringe and cold water, in order to free it completely of any débris that may have

been left behind. Unless this be done, a long time may elapse before the canal takes on healthy action, as the old granulations are too feeble to furnish reparative material.

Hammer.　　　Gouge.

osseous and soft, and occasionally requires plugging of the cavern with lint steeped in some styptic lotion, as a weak solution of subsulphate of iron, alum, or alum and tannic acid. It is seldom that any arteries require to be tied.

The edges of the wound are drawn lightly together with adhesive strips; the limb, placed in an easy position, is bandaged from the distal end upwards; and the parts more immediately affected are kept constantly wet with cold water medicated with laudanum and acetate of lead. The dressings are removed in forty-eight hours, when the wound is well syringed, and covered with an emollient poultice, to favor the granulating process. The only general means usually required are light diet and a little attention to the bowels, with a full anodyne after the patient is put to bed. If the new bone is not sufficiently strong to prevent the limb from bending or breaking, it must be supported by appropriate splints, or, what is better, a case made of sole-leather, gutta-percha, or trunk-maker's board. Extension and counter-extension may be necessary when there danger of shortening, as in necrosis of the thigh or leg. Ankylosis of the neighboring joints should be prevented or counteracted by passive motion.

The cicatrization will be greatly facilitated, after such an operation, if the edges of the cloacæ and sinuses be thoroughly pared before the parts are dressed, as they will thus be placed in a much better condition for the rapid development of healthy granulations. In general, the edges of such openings will be found to be livid, undermined, and partially devitalized, and, therefore, incapable of throwing out healthy material.

Soon after the sequester has been removed, whether by nature or art, the new osseous

shell begins to contract, and by degrees assumes the shape of the old bone, which it is designed to replace. While this change is going on externally, osseous matter is deposited upon the inner surface of the shell, as well as upon the articular ends of the surviving portions, thereby gradually filling up the cavity, the period required for this being generally in proportion to the size of the eschar. The medullary canal, in case there has been one, is, as already stated, seldom reëstablished.

It is not often that the surgeon is not able to effect a good cure in necrosis; in general, even with little deformity and loss of function. Cases do, however, occur, where, from neglect or injudicious treatment, the neighboring structures are so extensively and ruinously involved as to render it difficult, if not impossible, to save the affected limb. Such an event will be particularly liable to happen when a large joint is implicated, as, for instance, that of the knee in necrosis of the thigh, or of the ankle in necrosis of the tibia. Under such circumstances, hardly anything short of amputation will be likely to answer; and a similar procedure may become necessary when the patient's constitution is so much shattered by previous or concomitant disease as to preclude the possibility of its holding out during the time that may be required for the separation of the dead bone. In other cases, again, amputation may be demanded on account of hemorrhage from some large sinus, presenting itself either as a general oozing, or as a flow from an artery of considerable size, opened by ulcerative action at a period when the loss of a few more ounces of blood might prove fatal. Another reason for such interference is excessive deformity of the limb, rendering it not only very unseemly, but utterly unserviceable. It is impossible, however, to exercise too much caution in attempting to decide so grave a question. In weighing the several points involved in its consideration, we must not lose sight of the fact that cases, apparently of the most forlorn character, where life literally hangs, as it were, by a thread, will sometimes promptly recover upon the removal of the dead bone.

Resection of bone deprived of vitality may occasionally be advantageously practised instead of its removal in the form of a sequester. Such a procedure is especially indicated in young subjects exhausted by previous suffering, where delay would be likely to be followed by great damage to the constitution, if not destruction to life. Another advantage is that the periosteum may often be much better preserved than when the disease is left for several months to itself, as it must generally be when the bone is detached spontaneously. This whole subject has been placed in a very favorable light by Ollier, who, in in his great work, etitled Traité Expérimentale et Clinique de la Régénération des Os, published in 1867, has adduced a number of cases illustrative of the beneficial effects of this mode of treatment, derived chiefly from the practice of Larghi, Creus-y-Manzo, Jambon, Lentenneur, and T. Holmes, in all of which large portions of bone were removed, with the effect of useful limbs. Other instances, equally gratifying, have since been furnished, among others, one by Dr. Cheever and one by Dr. Buckingham, of Boston. The bone which yields the best results under this mode of treatment is the tibia, although it is applicable to every piece of the skeleton. Excision of the shaft of the tibia, however, is always followed, as was first pointed out by Ollier, by dislocation of the fibula at the superior tibio-fibular articulation, in consequence of the contraction of the muscles of the leg, whereby the head of this bone is gradually pushed beyond its natural level. This change was strikingly manifest in the case reported by Dr. Cheever. To counteract this tendency, proper mechanical appliances should be employed to insure perfect quietude of the limb until the parts are healed.

It occasionally happens that nature fails to repair the loss after the removal of the dead bone. In a case of this description, occurring in a child four years of age, in which two-thirds of the humerus were wanting, Dr. MacEwen, of Glasgow, transplanted small fragments of wedges of bone, obtained from the curved tibiæ of other patients, into the soft tissues, in the position of the deficiency, with the result of filling the gap with a new shaft, the limb being only half an inch shorter than its fellow. This ingenious practice has been imitated by Mr. Macnamara, of London, who inserted several grafts taken from an amputated metatarsus into a groove prepared in the leg of a child, from whom he had removed, some months previously, the greater part of the shaft of the tibia, but with what result I am not aware. That this operation is perfectly feasible is shown by some recent experiments of Bruns, in which the power of the cells of the medulla of the Haversian canals to form new bone is conclusively demonstrated.

SECT. X.—SOFTENING.

The essential characteristic of osteomalacia, mollities ossium, or softening of the bones, is a diminution of the firmness and solidity of the osseous tissue, depending upon the gradual removal of its earthy constituents, and the increase in its medullary elements. The disease is often confounded with rachitis, but differs from it in the circumstances, first, of its being a disorder of adult life, and, secondly, in being always attended with severe pain; whereas rickets is peculiar to infancy, and free from local suffering.

Fig. 392.

Madame Supiot, in a Posture quite practicable in the advanced Stage of the Disease.

Softening of the osseous tissue varies in degree and extent, occurring at one time as a very slight affection, with hardly an appreciable change of structure, and at another as a most serious lesion, in which it is difficult to distinguish any trace of the normal substance. In regard to its extent, it may be general or partial; in the one case pervading the entire skeleton, while in the other it is limited to particular bones, or even a portion of bone. Of general osteomalacia, the case of Madame Supiot, so minutely described by Morand, the younger, in the Memoirs of the Academy of Sciences of Paris, for 1710, affords a characteristic, as well as a most extraordinary, example, as shown in fig. 392. In this woman, who died at the age of thirty-seven, the bones were so completely softened that they could be bent like wax, and put in almost any position, although she herself had lost all control over them, her head and left arm being the only parts she could move. Most generally the disorder is confined to particular bones, as the ribs, sternum, vertebræ, and the pelvic pieces, the latter being especially liable to suffer in child-bearing women.

The osseous tissue in this disease gradually loses its firmness and solidity, becoming decalcified and ultimately so soft and pliant that it may be easily bent, if not cut. It is of a pale reddish color, often inclining to yellow, is specifically lighter than the healthy structure, and is infiltrated with a turbid, viscid serum, removable by pressure. Occasionally the osseous fibres are widely separated from each other, so as to leave large cells, which are filled with a bloody-looking, adipose substance, as seen in fig. 393. When this is the case, the bone is sometimes remarkably pliant, bending like semiconcrete wax. Boiling completely dissolves it; and exposure to the air, by abstracting its moisture, sensibly diminishes its weight. Such are the principal changes observable in the osseous tissue. The periosteum over the affected part is abnormally thick, rough, and but feebly adherent; it is of a grayish hue, deeply injected, and, like the bone, infiltrated with sanguinolent matter. Upon being macerated, however, it is found to retain its fibrous structure. The marrow is converted into a reddish, greasy sanies, and the medullary membrane is wasted away to a few soft, connective shreds. The cartilages sometimes participate in the softening, while the muscles are pale, atrophied, and infiltrated with a reddish fluid.

Fig. 393.

Section of a softened Femur; the Medullary and Cancellous Structures are occupied by a Transparent jelly-like Fat, of various Colors.

In the advanced stages of the disease, the bone is deprived of its laminated structure, the osseous corpuscles are greatly changed in their shape, as well as diminished in number, and the Haversian canals are enormously swollen and distended. The red, grumous substance, so abundantly diffused through its interior, has been shown by Dalrymple to consist of granular matter, nucleated cells, and caudate corpuscles.

The softening generally involves the whole thickness of the bone; but cases occur in which the outer table remains unchanged, consisting of a thin, brittle shell. The disorder obviously consists either in an inordinate absorption of the phosphate of lime upon which the solidity of the osseous structure naturally depends, or in a deficient deposition of this

matter into its meshes. Dr. Leeson, who has carefully investigated this subject, has found a specimen of softened bone to be composed of 18.75 of animal matter, 29.17 of phosphate and carbonate of lime, and 52.08 of water. As a general rule, it may be stated that there is always a notable increase of fatty matter, a diminution of phosphate and carbonate of lime, and an increase of animal substance.

Respecting the *causes* of osteomalacia our information is entirely at fault. It is generally supposed, and not without reason, that a gouty, rheumatic, syphilitic, or scorbutic state of the system predisposes to the occurrence. However this may be, it is evident that the disease is essentially connected with, if not directly dependent upon, a vitiated and depraved condition both of the solids and fluids; but whether the disorder of the one precedes that of the other, or whether they have a simultaneous origin, and afterwards keep steady and regular pace with each other, are questions which our knowledge is inadequate to solve. Whatever the real causes may be, it is a well ascertained fact that inflammation plays a most important part in the production of the changes which characterize it. If it were not so, how could we account for the excessive vascularity of the affected tissues, the sanguinolent nature of the infiltrated fluids, the thickened, spongy, and congested condition of the periosteum, and, finally, the atrocious and constant pains which form so notable a feature in the history of osteomalacia? All these circumstances unerringly point to inflammation as the great agent in the production of these changes; changes which, when existing in the soft structures, are invariably referred to this cause, and to none other. The morbid action, whatever it may be, is always of a chronic character, and is attended with important lesions of nutrition, leading to the removal of the earthy matter of the bones, and the excretion of it from the system, or its deposition among parts where it does not naturally occur. Or, what is more probable, there is both absorption of the original solid structure and a want of secretion of new, thus causing a complete disintegration, or decomposition, of the osseous tissue. All these circumstances are sufficiently obvious and tangible; but if we attempt to go beyond them, we involve ourselves at once in difficulties from which it is impossible to extricate ourselves.

Osteomalacia is rarely seen before the age of puberty, its favorite period of attack being between the thirtieth and fiftieth years. Another singular feature in its history is that it is much more frequent in women than in men, in the proportion, it has been said, of ten to three. Of 145 cases collected by Litzman, only 13 were males. It is most common in females who have borne several children; and it often begins either during pregnancy, or within a short time after parturition. Of the above cases, 91 were of this description. Examples have been reported in which it was hereditary, having been distinctly traced through three generations, but in none of the offspring did it show itself until after puberty. The bones of insane persons are frequently in a softened condition, approaching that of osteomalacia. At the Carmethen Asylum, as stated by Dr. Hernder, of twenty bodies examined after death, the ribs in nine were found to be abnormally soft and fragile.

The *symptoms* of this disease vary in its different stages. Its invasion and progress are generally very insidious. The earliest, and for a long time the most prominent, occurrence is pain in the limbs, spine, and pelvis, of a wandering, shifting character, which the patient usually supposes to be of a rheumatic nature, and which is often so severe as to cause immense distress, especially at night, and in damp, chilly states of the atmosphere. By and by, dyspnœa sets in, with palpitation of the heart, and a sense of constriction across the chest, and the patient is seized with an overwhelming feeling of prostration, which utterly unfits him for business, and usually compels him to keep his bed. If he attempts to walk, his limbs bend under him, and if the effort is often repeated, they soon become badly curved; should his toe catch in the folds of the carpet, or should he be so unfortunate as to trip, or fall, or give his body a sudden twist, he will probably hear some of his bones crack, and yield under the superincumbent weight. Emaciation gradually takes place, the appetite is deranged, the skin is bathed with clammy perspiration, the tongue is foul, the bowels are irregular, being either costive or too loose, and the urine, surcharged with earthy phosphates, is very thick, heavy, of a whitish aspect, and frequently also albuminous. In the latter stages of the malady, the saliva, tears, and sweat often contain similar ingredients. Great distortion frequently occurs; and the bones, bent in every direction, are effectually disqualified for the performance of their functions. The chest projects like that of a pigeon, the spine is bent laterally, as well as backwards, the pelvis is twisted, or rotated upon its axis, and the whole stature of the individual is sensibly diminished, the head being thrust down between the shoulders, which are unnaturally arched and prominent. Amidst all this disturbance, however, the intellect is unclouded, menstruation is perfect, and even conception is still possible. The period at

which death occurs varies from a few months to several years, its approaches being usually very gradual, and the consequence of sheer exhaustion.

The *diagnosis* of osteomalacia cannot always be very clearly defined. The disease for which it is most liable to be mistaken is rachitis, but from this it may generally be distinguished by the following circumstances :—Osteomalacia rarely occurs before the age of twenty-five or thirty, while rachitis is altogether peculiar to infancy and childhood, the disease in the former attacking the bones after the completion of ossification, whereas in the latter it assails them before they are fully developed. In softening, the patient is harassed with excessive pain and an overwhelming sense of exhaustion ; in rickets, on the contrary, there is a total absence of pain, and the little patient generally retains a good share of strength. In osteomalacia there is more deformity than in rachitis ; the disease is also of a more fatal character, few persons getting well, whereas in rachitis recovery is the rule, death the exception. Softening is much more common in women than in men, especially in such as have had several children ; rachitis, on the contrary, is nearly equally frequent in both sexes. In softening the urine always contains a large quantity of earthy matter, whereas in rickets this excretion is unusually laterititious. Finally, the two affections are signalized by marked differences in their anatomical characters. In osteomalacia the osseous structure is completely disintegrated and decomposed ; in rachitis, on the other hand, it is merely modified, and, therefore, susceptible of restoration.

The *prognosis* of osteomalacia is generally so unfavorable that Solly, Dalrymple, and some other authors are inclined to regard it as of a truly malignant character. Although this opinion requires confirmation, it serves to show how exceedingly unmanageable the disease has hitherto proved to be in the hands even of the best practitioners. The period at which death occurs is very variable, some patients dying in a few months, others not under several years.

The great point in the *treatment* of osteomalacia is to improve the general health by a well-regulated diet and by the employment of tonics, as iron and quinine, the shower-bath, and change of air. Mercury has occasionally been administered, and carried to the extent of ptyalism, but, instead of proving beneficial, it has usually been productive of injury by still further exhausting the powers of life. Phosphate of lime, as having a tendency to supply the deficiency of osseous matter, has also been tried, but apparently with no better effect. If we adopt the idea that the disease is of an inflammatory nature, antiphlogistics ought to be advantageous, but thus far their employment has yielded no good results, but rather the reverse. When the disease is fully established, confinement in bed upon a soft, elastic mattress will be necessary ; and every precaution should be taken to avoid the occurrence of curvature and fracture of the affected bones. Pain must be relieved by the liberal use of anodynes.

Fig. 394.

Rickets.

SECT. XI.—RACHITIS.

Rachitis, or rickets, is a disease of the osseous tissue, consisting in a deficiency both of its earthy and organic elements, as is shown by the diminished quantity of phosphate and carbonate of lime, and the absence of gelatin, which form such important constituents of normal bone. The consequence is that the different classes of bone, the long, short, and flat, become so excessively softened as, in time, to yield under the slightest pressure, bending and twisting in various directions, and thus occasioning serious and generally irremediable deformity, as observed in the drawing, fig. 394, taken from a patient at the Philadelphia Hospital.

Rickets, essentially a disease of early infancy, is most frequently witnessed from the eighteenth to the twentieth month, although many cases occur before the end of the first year. Now and then an instance is observed as late as the twelfth year ; but this is extremely uncommon, and altogether contrary to the usual course of the affection. Occasionally it is congenital. The influence

of age in the production of this affection is well shown by the combined statistics of Bruennische, Von Rittershain, and Ritsche, which indicate that of 903 cases, 358 occurred during the first year, 342 during the second, 134 during the third year, 31 during the fourth, 17 during the fifth year, and 21 from the sixth to the ninth. Instances have been noticed in which it seemed to be hereditary, or in which it attacked several members of the same family.

From the accurate and masterly account of this disease by Glisson, published upwards of two centuries ago, it appears that it first took its rise about the year 1620, in the western parts of England, from which it gradually spread over the rest of Europe. In this country it has always been extremely uncommon, even among the lower classes, whose children are its most frequent subjects. An exception, however, to this statement occurs in regard to the children of some of our eleëmosynary institutions. Thus, according to Dr. Parry, in the Philadelphia Hospital, 25 per cent. of all the children between two months and four years of age are rickety ; and in some of the foreign institutions, as in those of London, Prague, and other cities, the proportion is still greater. These differences are doubtless due to the differences of constitution, and modes of living, children that are crowded together, ill-fed, and confined in small, ill-ventilated apartments, being most liable to suffer from the disease.

Of the *causes* of rickets nothing is known. From the circumstance of its appearing occasionally in several members of the same family, it has by many been supposed to be of a hereditary character, nearly all of the older, and not a few of the modern, authorities concurring in this view of its origin. How far a strumous, or scorbutic state of the system is influential in its production is undetermined ; nor is anything positive known of the effects of a vitiated atmosphere upon its development, as living in damp, crowded, and ill-ventilated underground apartments, so prejudicial to the general health. That these and other causes may engender it when there is a predisposition to its occurrence is highly probable, but then the question arises, What creates the predisposition ? There must necessarily be some defect in the constitution, otherwise the disease could not take place. Mere disorder of the digestive and assimilative functions could not produce it, for thousands of children are thus affected, and yet do not suffer from rickets. A syphilitic taint of the system is a powerful factor in its production, as is shown by the fact that the majority of children born with congenital syphilis become ricketty despite the best nursing ; and Parrot, one of the latest writers on the subject, teaches that the disease can be traced to no other cause. Whatever the exciting cause may be, there is no question that the immediate one is a deficiency of phosphate and carbonate of lime, upon which the solidity of the osseous tissue essentially depends. How far the want of cartilage, which is such an important element of healthy bone, may disqualify the osseous tissue in rachitis for the reception of earthy matter, is a problem which remains to be solved.

The *pathological* alterations of the osseous tissue consequent upon this disease may be conveniently arranged under three heads, each possessing marked peculiarities. In the first, the bones are saturated with a reddish, watery fluid, a considerably quantity of which is also interposed between their outer surface and the periosteum, on the one hand, and between the medullary membrane and their internal walls, on the other. At a more advanced period, this fluid is replaced by a sort of gelatiniform substance, which becomes gradually organized, and ultimately adheres with great firmness to the parts with which it lies in contact. The periosteum is thickened and injected, the nutrient vessels are remarkably enlarged, and the medullary membrane is very spongy and vascular. The lamellæ of the long bones, naturally so hard and compact, are a good deal softened, while the areolar structure is greatly rarefied, many of the cells being more than double the natural size. Similar alterations are observed in the short and flat bones.

In the second stage, a peculiar spongoid substance is formed between the periosteum and the outer surface of the bones, varying from two to three lines, or upwards, in thickness. When the quantity of this "transition tissue" is unusually great, it may exert such a degree of pressure upon the lamellæ of the compact tissue as to push them inwards towards the medullary canal, in such a manner as to reduce it very materially in size, if it do not entirely obliterate it. Simultaneously with these changes the bones are rendered so soft that they may easily be bent, cut, and even indented with the finger.

In the third stage, that of resolution, the recently formed substance in the long bones, as well as in some of the flat and short, assumes a compact character, and is gradually identified with the preëxisting tissues, which at the same time regain their primitive solidity. Owing to the presence of this new matter, the bones are much larger than in

their natural state, and their firmness, especially in the adult, resembles that of ivory. Hence the term eburnation is sometimes applied to this condition.

When rachitis proves fatal, the body is usually found in a state of excessive emaciation; the muscles are thin, pale, and flabby; the ligaments are relaxed; the adipose matter is almost entirely consumed; the cerebral substance is unnaturally soft; the liver and spleen are enlarged and flaccid; the intestines are attenuated and distended with gas, and there is not unfrequently marked tumefaction of the muciparous follicles; the mesenteric glands are increased in volume and consistence; the heart is softened, and smaller than common; the lungs, which are often congested, are more or less tuberculized in about one-sixth of the cases; and the bronchial glands are hypertrophied, loaded with serosity, and of a deep purplish hue. Occasionally there is partial ossification of the arteries, muscles, and other structures, as if they had become the recipients of the earthy matter which naturally appertains to the bones.
